AIEE Transactions Index for 1949

(Complete Index for Parts I and II of Volume 68)

1. Technical Subject Index

Accessory Design Utilizing New Laboratory Techniques, Cable. Bosworth, Farr.......1268–73; disc. 1273
Adjustable-Speed Drive, A Wide-Range. Conrad, Tribken..........789–90
Adjustable Speed Motors, Limitations in Design of D-C. Opel..........1095–8
Adjusting Radiosonde Recorder, Automatic Range-. Beggs..........602–07
Advances in Technique of Lightning Measurements. Brownlee..........515–19
AIEE-ASME Governor Performance Specification, Governors and the. Schwendner, Astley...1330–2
Ailments, Diagnosis of Rectifier. Dortort....1298–1304
Air-Break Switches for Protection of Transformer Stations, Automatic Grounding and. Ricker..........851–6; disc. 856
Air Circuit Breaker, A New 69-Kv Compressed-. Baker, Frisch..........363–8; disc. 369
Air-Core Reactors as Fault Limiting Means on High Interrupting Capacity Controllers, The Use of. Leitch..........469–74; disc. 474
Aircraft, An Electric Deicing System for. Gilloy..........1051–7
Aircraft Cable, Current Ratings of. Askew, McClinton..........988–92
Aircraft Carbon-Pile Voltage Regulators, Fundamentals, and Design Improvements. Austin, Richards..........983–7
Aircraft, Lightning Stroke Damage to. Hagenguth..........1036–44; disc. 1044
Aircraft Propellers, Development and Application of Electric Heating to Deicing of. Sheets, Sand..........1068–72
Aircraft Transformers, Lightweight. Stephens..1073–8
Airplane Main Bus, Protection of the. Exner..........979–82
Alarm and Control System for Remote Control of Coaxial Cable Stations, B-1. Hearn, Weber...622–6
A-C Generators, A Semiempirical Approach to Voltage Dip—with Suddenly Applied Loads on. Rosenberg..........160–6; disc. 166
A-C Network Analyzer, An Improved. Morgan, Rothe, Winsness..........891–5; disc. 895
A-C Resistance of Segmental Cables in Steel Pipe. Meyerhoff, Eager..........816–29; disc. 829
A-C Tripping and Reclosing of Line Sectionalizing Circuit Breakers. Winegartner, Bonheimer...1357–9
A-C Voltmeter, A New Expanded Scale. Millar..........641–3
Altitudes, A Small High-Voltage Bushing Design for High. Vogel, Hart..........761–4
Ampere Demand Meter, A New Thermal Volt-. Douglass, Morong..........79–83; disc. 83
Amplifier—Class A Operation, The Dynamoelectric. Saunders..........1368–73
Amplifier Stabilized for Gain and for Zero, Wide-Band D-C. Williams, Amey, McAdam..........811–15; disc. 815
Amplifiers, An Analysis of Rotating. Litman..1111–17
Amplifiers with Feedback, Analytical Determination of Characteristics of Magnetic. VerPlanck, Finzi, Beaumariage..........565–70
Amplifiers, Self-Saturation in Magnetic. Dornhoefer..........835–46; disc. 846
Analog Computer to Nonlinear Mechanics and Servomechanisms, Application of the California Institute of Technology Electric. McCann, Wilts, Locanthi..........652–60
Analog Computers, Comparison of Long-Time and Short-Time. Paschkis..........70–3
Analogs of Linear Vibration Problems, Summary of Transformations Useful in Constructing. Corbett..........661–4
Analogy, The Transient Behavior of the Two-Stage Rototrol Main Exciter Voltage Regulating System as Determined by Electrical. Carleton.....59–63
Analysis of Relay Servomechanisms, An. Kahn..........1079–87; disc. 1087
Analysis of Results to Research Problems in Magnetic Recording, Application of Experimental Test Procedures and Methods of. Thompson......407–17
Analysis of Rotating Amplifiers, An. Litman..1111–17
Analysis, The Torques of the Synchronous Tie—A Steady-State. Finzi, McConnell..........1147–52
Analytical Co-ordination Method, Field Tests of Oil Circuit Recloser Substantiate. Auer, Branflick, Woodward, McKinley..........801–08; disc. 808
Analytical Determination of Characteristics of Magnetic Amplifiers with Feedback. VerPlanck, Finzi, Beaumariage..........565–70
Analyzer, A New Fourier Coefficient Harmonic. Charp..........644–9; disc. 649
Analyzer, An Improved A-C Network. Morgan, Rothe, Winsness..........891–5; disc. 895
Analyzer to Determine Plant Loading Schedules, Coordination of Fuel Cost and Transmission Loss by Use of the Network. George, Page, Ward..........1152–60; disc. 1160
Application Engineering on Diesel-Electric Locomotives in Railroad Service. Bevan..........125–31
Application of Electric Heating to Deicing of Aircraft Propellers, Development and. Sheets, Sand..........1068–72
Application of Experimental Test Procedures and Methods of Analysis of Results to Research Problems in Magnetic Recording. Thompson..........407–17
Application of Multifrequency Pulsing in Switching. Dahlbom, Horton, Moody..........392–6
Application of the California Institute of Technology Electric Analog Computer to Nonlinear Mechanics and Servomechanisms. McCann, Wilts, Locanthi..........652–60
Applications, Microwave Channels for Power System. (Committee Report)..........40–2; disc. 42
Applications, Two Gas Turbines for Power Generation and Other. Howard..........461–5; disc. 465
Approach to the Design of High-Voltage Cable Joints, A Theoretical and Practical. Short..........1275–80; disc. 1280
Arc, Instrumentation for the Evaluation of the Stability of the Welding. Winsor, Schetky, Wyant..525–33
Arc Paths, Deionization Time of High-Voltage Fault. Harrington, Starr..........997–1003; disc. 1003
Armature Iron Losses in Series Motors. Chang, Karr..........262–4; disc. 264
Arrangements and Protective Practices for Shunt Capacitor Banks, Connection. Clark, Farnham..........1226–30; disc. 1231
ASME Governor Performance Specification, Governors and the AIEE-. Schwendner, Astley......1330–2
Aspects of Relay Circuits, Sequential. Ritchie..577–81
Attenuation and Delay Equalizers for Coaxial Lines. Lundry..........1174–9
Audio Noise Problems on an Electric Power System, Transformer. Murray..........740–7; disc. 747
Automatic Control Systems, The Design of D-C Motors for Use in. Lebenbaum..........1089–94
Automatic Grounding and Air-Break Switches for Protection of Transformer Stations. Ricker..........851–6; disc. 856
Automatic Load Control for Turbine Generators, A New. Ruud, Farnham.......1337–42; disc. 1342
Automatic Range-Adjusting Radiosonde Recorder. Beggs..........602–07
Auxiliary Circuits of Single-Phase Induction Motors, Design of. Thacker, Gopalakrishna.......1373–9

B

B-1 Alarm and Control System for Remote Control of Coaxial Cable Stations. Hearn, Weber.....622–6
Backlash, Instrument Inaccuracies in Feed-Back Control Systems with Particular Reference to. Marcy, Yachter, Zauderer..........778–88
Band Coupling of Power-Line Carrier Equipment, A Proposal for Broad-. Miller...1028–30; disc. 1030
Band D-C Amplifier Stabilized for Gain and for Zero, Wide-. Williams, Amy, McAdam..........811–15; disc. 815
Band of Governors on Steam Turbine Generators Under System Load Conditions, Determining Incremental Regulation and Dead. Tornquist, Wade..1343–7
Bandwidths, The Distinction Between Effective and Circuit. Kessler..........98–9
Bank, The Temperature Rise of Cables in a Duct. Neher..........540–6; disc. 546
Banks, Connection Arrangements and Protective Practices for Shunt Capacitor. Clark, Farnham..........1226–30; disc. 1231
(Basic Sciences) A Derivation of Heaviside's Operational Calculus Based on the Generalized Functions of Schwartz. Smith, Alger........939–44; disc. 944
(Basic Sciences) Dielectric Strength of Oil with Variations of Pressure and Temperature. Hoover, Hixson..........1047–50
(Basic Sciences) Formulas and Tables for the Calculation of the Magnetic Field Components of Circular Filaments and Solenoids. Grover..........665–75
(Basic Sciences) General Theory, and Experimental Confirmation, of the Moving Coil Fluxmeter. Higgins, Robertson..........897–907; disc. 907
(Basic Sciences) Nonharmonic Oscillations as Caused by Magnetic Saturation. Rudenberg..........676–85
(Basic Sciences) Self-Saturation in Magnetic Amplifiers. Dornhoefer..........835–46; disc. 846.
(Basic Sciences) The Vector Power Factor of Unbalanced Sinusoidal 3-Phase Circuits. Lamb, Brandt..........507–09
Behavior of the Two-Stage Rototrol Main Exciter Voltage Regulating System as Determined by Electrical Analogy, The Transient. Carleton..........59–63
Board of Directors, Report of the..........1383–1408
Boilers and of Hydro Units, Outage Rates of Steam Turbines and. (Committee Report)........450–7
Bolometer, Detection of Overheated Transmission Line Joints by Means of a. Leslie, Wait..64–8; disc. 68
Bonneville Power Administration Transmission System, Matching Electrical Characteristics of McNary Generators and Transformers with. Hoard, Weiner..........1022–5; disc. 1026
Braking Control of D-C Series Motors—Experimental Study of Speed-Torque Curves, Dynamic. Heumann..........560–4
Breaker, A New 69-Kv Compressed-Air Circuit. Baker, Frisch..........363–8; disc. 369
Breakers, A Manually-Operated Spring Mechanism for Medium Voltage Oilless Circuit. Wyman, Casey..........357–61; disc. 361
Breakers, A-C Tripping and Reclosing of Line Sectionalizing Circuit. Winegartner, Bonheimer....1357–9
Breakers, Insulator Flashover Deionization Times as a Factor in Applying High-Speed Reclosing Circuit. Boisseau, Wyman, Skeats......1058–66; disc. 1066
Broad-Band Coupling of Power-Line Carrier Equipment, A Proposal for. Miller.......1028–30; disc. 1030
Brushes, Progress Report on AIEE Test Code for Electric. (Committee Report)..........1126–8
Buried Cables and Pipes, The Temperature Rise of. Neher..........9–17; disc. 17
Bus, Protection of the Airplane Main. Exner...979–82
Bushing Design for High Altitudes, A Small High-Voltage. Vogel, Hart..........761–4
Busses, Trolley Coaches Replace. McMillon...403–06

C

Cable Accessory Design Utilizing New Laboratory Techniques. Bosworth, Farr......1268–73; disc. 1273
Cable Circuits in Philadelphia, 69-Kv Pipe-Type. Kidder, Van Antwerp..........550–6; disc. 556
Cable, Current Ratings of Aircraft. Askew, McClinton..........988–92
Cable for Carrier Current Installation on Power Lines, Line Tuning Equipment Used With Coaxial. Sutton..........44–8; disc. 48
Cable Impregnated with Extra-High-Viscosity Oil, High-Pressure Gas-Filled. Sticher, Doan, Atkinson, Meyerhoff..........336–45; disc. 345
Cable Joints, A Theoretical and Practical Approach to the Design of High-Voltage. Short..........1275–80; disc. 1280
Cable Overhead-Conductor 132-Kv Transmission Line at Carrier Current Frequencies, Loss Measurements Made on Underground-. Cornelius, Storer..........597–601
Cable Stations, B-1 Alarm and Control System for Remote Control of Coaxial. Hearn, Weber...622–6
Cables and Pipes, The Temperature Rise of Buried. Neher..........9–17; disc. 17
Cables, Heating of Radio-Frequency. Macalpine..........283–8
Cables in a Duct Bank, The Temperature Rise of. Neher..........540–6; disc. 546
Cables in Steel Pipe, A-C Resistance of Segmental. Meyerhoff, Eager..........816–29; disc. 829
Cables, The Power Rating of Radio-Frequency. Mildner..........289–98; disc. 298
Cables, Transient Temperature Phenomena of 3-Conductor. Wollaston..........1284–95; disc. 1295
Cage Induction Motors, General Theory of Multiple. Chang..........1139–43

Calculated Risk of Operating Capacitors Without Individual Fuses, The. Brooks....1219–25; disc. 1225
Calculation of the Magnetic Field Components of Circular Filaments and Solenoids, Formulas and Tables for the. Grover........................665–75
Calculus Based on the Generalized Functions of Schwartz, A Derivation of Heaviside's Operational. Smith, Alger...................939–44; disc. 944
California Institute of Technology Electric Analog Computer to Nonlinear Mechanics and Servomechanisms, Application of the. McCann, Wilts, Locanthi..652–60
Capacitor Banks, Connection Arrangements and Protective Practices for Shunt. Clark, Farnham..................................1226–30; disc. 1231
Capacitors, Report of a Survey on the Performance of Shunt. (Committee Report)..1200–06; disc. 1206
Capacitors, Report on the Operation and Maintenance of Shunt. (Committee Report)..........1208–18
Capacitors Without Individual Fuses, The Calculated Risk of Operating. Brooks....1219–25; disc. 1225
Capacity Controllers, The Use of Air-Core Reactors as Fault Limiting Means on High Interrupting. Leitch........................469–74; disc. 474
Carbon-Pile Voltage Regulators, Fundamentals, and Design Improvements, Aircraft. Austin, Richards..983–7
Carrier Current Frequencies, Loss Measurements Made on Underground-Cable Overhead-Conductor 132-Kv Transmission Line at. Cornelius, Storer..597–601
Carrier Current Installation on Power Lines, Line Tuning Equipment Used With Coaxial Cable for. Sutton..............................44–8; disc. 48
(Carrier Current) Microwave Channels for Power System Applications. (Committee Report)..40–2; disc. 42
Carrier Equipment, A Proposal for Broad-Band Coupling of Power-Line. Miller..1028–30; disc. 1030
Carrier for Relaying and Joint Usage, Power Line. Part I. Hampe, Storer..........864–7; disc. 867
Carrier System, Stability of Tandem Regulators in the L-1. Kinzer..........................1179–86
Centralized Traffic Control for Railroads. Hailes..1167–73
Changing Temperature, The Measurement of Dielectric Loss at High Frequencies and Under. Whitehead, Rueggeberg..............................520–4
Channels for Power System Applications, Microwave. (Committee Report)...............40–2; disc. 42
Characteristics of D-C Motors and Generators, Transient. McClinton, Brancato, Panoff......1100–06
Characteristics of Distribution Systems, Voltage-Recovery. Witzke.................172–80; disc. 180
Characteristics of Lightning Protective Devices, Performance. (Committee Report)..............1333–6
Characteristics of Magnetic Amplifiers with Feedback, Analytical Determination of. VerPlanck, Finzi, Beaumariage..............................565–70
Characteristics of McNary Generators and Transformers with Bonneville Power Administration Transmission System, Matching Electrical. Hoard, Weiner..................................1022–5; disc. 1026
Characteristics of Two-Phase Servomotors, Operating. Koopman......................319–27; disc. 327
Characteristics, Rectifier Transformer. (Committee Report)..............................1305–11
Charged Dust in Rooms, Electrically. Penney, Hewitt..278–82
Charging Currents on Transmission Lines as Affecting Ground-Fault Neutralizers, Report on Survey of Unbalanced. (Committee Report)..1328; disc. 1329
Chart Methods Applied to Frequency Response Curves, Control. Mundel........................424–7
Chesapeake and Ohio Railway Company Steam Turbine-Electric Locomotives, Electric Equipment for. Atwell, Baston..............................145–8
Circuit Bandwidths, The Distinction Between Effective and. Kessler..............................98–9
Circuit Breaker, A New 69-Kv Compressed-Air. Baker, Frisch..........................363–8; disc. 369
Circuit Breakers, A Manually-Operated Spring Mechanism for Medium Voltage Oilless. Wyman, Casey..........................357–61; disc. 361
Circuit Breakers, A-C Tripping and Reclosing of Line Sectionalizing. Winegartner, Bonheimer...1357–9
Circuit Breakers, Insulator Flashover Deionization Times as a Factor in Applying High-Speed Reclosing. Boisseau, Wyman, Skeats......1058–66; disc. 1066
Circuit Conditions, Heating of Transformers Under Short-. Montsinger, Halsey.....947–52; disc. 952
Circuit Currents and Recovery Voltages on Rural Distribution Systems, Short-. Eason, Johnson, Kalb, Peterson..........................930–7; disc. 937
Circuit of D-C Motors and Generators, Solid Short. Linville, Ward.................119–23; disc. 123
Circuit Recloser Substantiate Analytical Co-ordination Method, Field Tests of Oil. Auer, Branflick, Woodward, McKinley...............801–08; disc. 808
Circuits for Power-Flow Studies, Equivalent. Ward..373–80; disc. 380
Circuits for Protective Relays, Novel Test. Sonnemann..1249–54
Circuits in Philadelphia, 69-Kv Pipe-Type Cable. Kidder, Van Antwerp...........550–6; disc. 556
Circuits, Insulation Level of Relay and Control. (Committee Report)..........................1255–7
Circuits of Single-Phase Induction Motors, Design of Auxiliary. Thacker, Gopalakrishna.......1373–9
Circuits, Relay "Trees" and Symmetric. Washburn..582–6
Circuits, Sequential Aspects of Relay. Ritchie..577–81
Circuits, The Logic of Relay. Keister..........571–6
Circuits, The Vector Power Factor of Unbalanced Sinusoidal 3-Phase. Lamb, Brandt..........507–09
Circular Filaments and Solenoids, Formulas and Tables for the Calculation of the Magnetic Field Components of. Grover........................665–75
Clamps, Magnetic Heating of Transmission Line. Crabb, Sheadel..........................1032–5
Class A Operation, The Dynamoelectric Amplifier—. Saunders..............................1368–73
Class-H Insulation and Silicone Varnish, Motor Tests Evaluate Thermal Endurance of. Grant, Kauppi, Moses, Gibson..............................1133–8
Coaches Replace Busses, Trolley. McMillon...403–06
Coaxial Cable for Carrier Current Installation on Power Lines, Line Tuning Equipment Used With. Sutton..............................44–8; disc. 48
Coaxial Cable Stations, B-1 Alarm and Control System for Remote Control of. Hearn, Weber.....622–6
Coaxial Lines, Attenuation and Delay Equalizers for. Lundry..............................1174–9
Coaxial Lines, Equalization of. Gould.......1187–92
Coaxial Systems, Power Supplies for. Spencer...627–30
Coaxial Systems, Television Terminals for. Morrison..1193–9
Code for Electric Brushes, Progress Report on AIEE Test. (Committee Report)..............1126–8
Code Selector Supervisory System, Space. Forrest, Schirmer..................1312–15; disc. 1315
Codes and Translations. Myers...............592–7
Coefficient Harmonic Analyzer, A New Fourier. Charp..............................644–9; disc. 649
Coil Fluxmeter, General Theory and Experimental Confirmation of the Moving. Higgins, Robertson..................................897–907; disc. 907
(Committee Report) Insulation Level of Relay and Control Circuits..............................1255–7
(Committee Report) Microwave Channels for Power System Applications..............40–2; disc. 42
(Committee Report) Outage Rates of Steam Turbines and Boilers and of Hydro Units............450–7
(Committee Report) Performance Characteristics of Lightning Protective Devices.............1333–6
(Committee Report) Progress Report on AIEE Test Code for Electric Brushes..................1126–8
(Committee Report) Protection of Stations Without High-Voltage Switching........226–31; disc. 231
(Committee Report) Rectifier Transformer Characteristics..............................1305–11
(Committee Report) Report of a Survey on the Performance of Shunt Capacitors......1200–06; disc. 1206
(Committee Report) Report on Survey of Unbalanced Charging Currents on Transmission Lines as Affecting Ground-Fault Neutralizers....1328; disc. 1329
(Committee Report) Report on the Operation and Maintenance of Shunt Capacitors.............1208–18
(Committee Report) Stray Load Losses Measured in D-C Motors..................219–23; disc. 223
(Committee Report) Temperature Rise Values for D-C Machines. Part I.............206–12; disc. 212
(Committee Report) Temperature Rise Values for D-C Machines. Part II..........1118–23; disc. 1123
Committees and Officers—1949–1950..........1409–28
(Communication) A Method for Designing Pulse Transformers. Kirschbaum, Warren............971–8
(Communication) A Time Division Multiplexing System. Boothroyd, Creamer.................92–7
(Communication) Application of Experimental Test Procedures and Methods of Analysis of Results to Research Problems in Magnetic Recording. Thompson..............................407–17
(Communication) Application of Multifrequency Pulsing in Switching. Dahlbom, Horton, Moody...392–6
(Communication) Attenuation and Delay Equalizers for Coaxial Lines. Lundry................1174–9
(Communication) B-1 Alarm and Control System for Remote Control of Coaxial Cable Stations. Hearn, Weber..............................622–6
(Communication) Centralized Traffic Control for Railroads. Hailes..........................1167–73
(Communication) Codes and Translations. Myers..592–7
(Communication) Considerations on Facsimile Transmission Speed. Burkhard.......418–23; disc. 423
(Communication) Control Chart Methods Applied to Frequency Response Curves. Mundel......424–7
(Communication) Counting with Relays. Frost..587–91
(Communication) Equalization of Coaxia Lines. Gould..............................1187–92
Communication Equipment for Land-Mobile Services Operating on Frequencies Between 152–174 Megacycles, Design of Mobile Radio. Beers, Harris, Zappacosta..............................1232–9
(Communication) Power Supplies for Coaxial Systems. Spencer..............................627–30
(Communication) Power Supplies for Microwave Relay Systems. Ward..........................631–6
(Communication) Radio Influence from High-Voltage Corona. Slemon..............198–204; disc. 204
Communication Relay System, A Microwave. Boothroyd, Churchill..........................637–41
(Communication) Relay "Trees" and Symmetric Circuits. Washburn..........................582–6
(Communication) Rubber Insulators for Pole Lines. Wheeler, Markley..........................195–7
(Communication) Sequential Aspects of Relay Circuits. Ritchie..............................577–81
(Communication) Stability of Tandem Regulators in the L-1 Carrier System. Kinzer.........1179–86
(Communication) Television Terminals for Coaxial Systems. Morrison.......................1193–9
(Communication) The Distinction Between Effective and Circuit Bandwidths. Kessler...........98–9
(Communication) The Logic of Relay Circuits. Keister..571–6
(Communication) Vibrating Reed Selective Signaling System for Mobile Telephone Use. Pruden, Hoth..387–91
(Communication) Vibrating Reed Selectors for Mobile Radio Systems. Keller, Bostwick...........383–6
Commutation of D-C Machines and Its Effects on Radio Influence Voltage Generation. Motter..................................491–5; disc. 495
Commutation, Oscillographing. Baldwin..................................100–05; disc. 105
Commutation with an Indicating Instrument, Measuring. Lundy..............................1380–2
Commutator Surface Film Conditions on Commutation, Effects of. Lynn, Elsey........106–112; disc. 112
Comparative Performance Records—Steel and Wood Transmission Lines. Booker......686–9; disc. 689
Comparison of Long-Time and Short-Time Analog Computers. Paschkis..............................70–3
Comparison of Steady-State and Transient Performance of Servomechanisms. Chestnut, Mayer....765–77
Components and Systems, Graphical Determination of Transfer Function Loci for Servomechanism. Thomas, Easton................307–14; disc. 314
Components of Circular Filaments and Solenoids, Formulas and Tables for the Calculation of the Magnetic Field. Grover..............................665–75
Compressed-Air Circuit Breaker, A New 69-Kv. Baker, Frisch........................363–8; disc. 369
Computer to Nonlinear Mechanics and Servomechanisms, Application of the California Institute of Technology Electric Analog. McCann, Wilts, Locanthi..............................652–60
Computers, Comparison of Long-Time and Short-Time Analog. Paschkis..............................70–3
(Computing Devices) An Improved A-C Network Analyzer. Morgan, Rothe, Winsness..891–5; disc. 895
(Computing Devices) Summary of Transformations Useful in Constructing Analogs of Linear Vibration Problems. Corbett..............................661–4
Conditions, Determining Incremental Regulation and Dead Band of Governors on Steam Turbine Generators Under System Load. Tornquist, Wade..1343–7
Conditions During Operation of Hydroelectric Units, Some Oscillographic Methods of Investigating Mechanical and Hydraulic. Engvall.......993–6
Conditions, Fundamental Theory of Inherent-Overheating Protection Under Running Overload. Veinott, Schaefer..........................266–70; disc. 270
Conditions, Heating of Transformers Under Short-Circuit. Montsinger, Halsey.......947–52; disc. 952
Conditions on Commutation, Effects of Commutator Surface Film. Lynn, Elsey......106–12; disc. 112
Conductor Cables, Transient Temperature Phenomena of 3-. Wollaston............1284–95; disc. 1295
Conductor Economics, Distribution Transformer and Secondary. Brady..............483–6; disc. 486
Conductor, Hy-Therm Copper—Improved Overhead Line. Hickernell, Jones, Snyder.....22–7; disc. 27
Conductor 132-Kv Transmission Line at Carrier Current Frequencies, Loss Measurements Made on Underground-Cable Overhead-. Cornelius, Storer..597–601
Confirmation of the Moving Coil Fluxmeter, General Theory and Experimental. Higgins, Robertson..................................897–907; disc. 907
Connection Arrangements and Protective Practices for Shunt Capacitor Banks. Clark, Farnham..................................1226–30; disc. 1231
Considerations on Facsimile Transmission Speed. Burkhard..........................418–23; disc. 423
Contaminants on Electrical Insulation, Methods for Determining the Effects of. Mathes, Sieffert, Walker, Lindsey................113–18; disc. 118

Control Chart Methods Applied to Frequency Response Curves. Mundel.....424–7
Control Circuits, Insulation Level of Relay and. (Committee Report).....1255–7
Control for Railroads, Centralized Traffic. Hailes.....1167–73
Control for Turbine Generators, A New Automatic Load. Ruud, Farnham.....1337–42; disc. 1342
Control of D-C Series Motors—Experimental Study of Speed-Torque Curves, Dynamic Braking. Heumann.....560–4
Control System, A New 2-Signal Synchronous Supervisory. Derr.....857–63; disc. 863
Control System for Remote Control of Coaxial Cable Stations, B-1 Alarm and. Hearn, Weber.....622–6
Control Systems, The Design of D-C Motors for Use in Automatic. Lebenbaum.....1089–94
Control Systems with Particular Reference to Backlash, Instrument Inaccuracies in Feed-Back. Marcy, Yachter, Zauderer.....778–88
Controllable Reactors, Universal Curves for D-C. Johnson, Merrell, Alley.....31–7; disc. 37
Controlled Reactors with Resistive Load, Some Fundamentals of D-C. Storm.....188–94; disc. 194
Controlled Temperature and Insulation Protection in the Operation of Power Transformers. Satterlee, Reed.....753–8; disc. 759
Controllers, The Use of Air-Core Reactors as Fault Limiting Means on High Interrupting Capacity. Leitch.....469–74; disc. 474
Convenient Method for Determining Generator Reserve, A. Seelye.....1317–20
Converter for Telemetering and Totalizing, A Thermal. Downing.....879–84; disc. 884
Co-ordination Method, Field Tests of Oil Circuit Recloser Substantiate Analytical. Auer, Branflick, Woodward, McKinley.....801–08; disc. 808
Co-ordination of Fuel Cost and Transmission Loss by Use of the Network Analyzer to Determine Plant Loading Schedules. George, Page, Ward.....1152–60; disc. 1160
Co-ordination of Oil Insulated Transformers, Extremes in the Insulation. Vogel.....965–8; disc. 968
Copper—An Improved Overhead-Line Conductor, Hy-Therm. Hickernell, Jones, Snyder.....22–7; disc. 27
Corona, Radio Influence from High-Voltage. Slemon.....198–204; disc. 204
Cost and Transmission Loss by Use of the Network Analyzer to Determine Plant Loading Schedules, Coordination of Fuel. George, Page, Ward.....1152–60; disc. 1160
Counting with Relays. Frost.....587–91
Coupling of Power-Line Carrier Equipment, A Proposal for Broad-Band. Miller.....1028–30; disc. 1030
Cumulative and Differential Series Fields in the Parallel Operation of D-C Motors, Use of. Kimball.....1098–1100
Current Frequencies, Loss Measurements Made on Underground-Cable Overhead-Conductor 132-Kv Transmission Line at Carrier. Cornelius, Storer.....597–601
Current Installation on Power Lines, Line Tuning Equipment Used With Coaxial Cable for Carrier. Sutton.....44–8; disc. 48
Current Ratings of Aircraft Cable, Askew, McClinton.....988–92
Currents and Recovery Voltages on Rural Distribution Systems, Short-Circuit. Eason, Johnson, Kalb, Peterson.....930–7; disc. 937
Currents on Transmission Lines as Affecting Ground-Fault Neutralizers, Report on Survey of Unbalanced Charging. (Committee Report)..1328; disc. 1329
Currents, Rectifier Fault—II. Herskind, Schmidt, Rettig.....243–51; disc. 251
Curves, Control Chart Methods Applied to Frequency Response. Mundel.....424–7
Curves, Dynamic Braking Control of D-C Series Motors—Experimental Study of Speed-Torque. Heumann.....560–4
Curves for D-C Controllable Reactors, Universal. Johnson, Merrell, Alley.....31–7; disc. 37
Cycle Out-of-Step Relay Equipment, One Slip. Morris.....1246–8

D

Damage to Aircraft, Lightning Stroke. Hagenguth.....1036–44; disc. 1044
Damper Stabilized Instrument Servomechanisms. Hall.....299–306; disc. 306
Data, Prediction of Ultimate Temperature Rise from Early Heat Run. Ryan.....1164–6
Dead Band of Governors on Steam Turbine Generators Under System Load Conditions, Determining Incremental Regulation and. Tornquist, Wade.....1343–7
Deicing of Aircraft Propellers, Development and Application of Electric Heating to. Sheets, Sand.....1068–72
Deicing System for Aircraft, An Electric. Giloy.....1051–7
Deionization Time of High-Voltage Fault-Arc Paths. Harrington, Starr.....997–1003; disc. 1003
Deionization Times as a Factor in Applying High-Speed Reclosing Circuit Breakers, Insulator Flashover. Boisseau, Wyman, Skeats.....1058–66; disc. 1066
Delay Equalizers for Coaxial Lines, Attenuation and. Lundry.....1174–9
Demand Meter, A New Thermal Volt-Ampere. Douglass, Morong.....79–83; disc. 83
Demand Meters, Heat Flow Ratio as a Design Parameter in Thermal. Nelson.....885–90; disc. 890
Derivation of Heaviside's Operational Calculus Based on the Generalized Functions of Schwartz, A. Smith, Alger.....939–44; disc. 944
Design and Experience with 4-Kv Primary Network Systems in the Washington Area. Lank.....712–16; disc. 716
Design and Performance Based on Direct Lightning Strokes, Transmission Line. Harder, Clayton.....439–46; disc. 447
Design and Ventilation, Transformer Manholes and Vaults: Porter.....534–9
Design Features—Steam-Electric Generating Station P of the Pacific Gas and Electric Company, Electrical. Benson.....1013–20; disc. 1020
Design for High Altitudes, A Small High-Voltage Bushing. Vogel, Hart.....761–4
Design Fundamentals of Potheads 69,000 Volts and Below. Nicholas.....1263–7; disc. 1267
Design Improvements, Aircraft Carbon-Pile Voltage Regulators, Fundamentals, and. Austin, Richards.....983–7
Design of Auxiliary Circuits of Single-Phase Induction Motors. Thacker, Gopalakrishna.....1373–9
Design of D-C Adjustable Speed Motors, Limitations in. Opel.....1095–8
Design of D-C Motors for Use in Automatic Control Systems, The. Lebenbaum.....1089–94
Design of High-Voltage Cable Joints, A Theoretical and Practical Approach to the. Short.....1275–80; disc. 1280
Design of Mobile Radio Communication Equipment for Land-Mobile Services Operating on Frequencies Between 152–174 Megacycles. Beers, Harris, Zappacosta.....1232–9
Design of Traction Motors, Twenty-Five Years Progress in the. Baldwin.....132–7
Design Parameter in Thermal Demand Meters, Heat Flow Ratio as a. Nelson.....885–90; disc. 890
Design Utilizing New Laboratory Techniques, Cable Accessory. Bosworth, Farr.....1268–73; disc. 1273
Designing Pulse Transformers, A Method for. Kirschbaum, Warren.....971–8
Detection of Overheated Transmission Line Joints by Means of a Bolometer. Leslie, Wait. 64–8; disc. 68
Determination of Characteristics of Magnetic Amplifiers with Feedback, Analytical. VerPlanck, Finzi, Beaumariage.....565–70
Determination of Transfer Function Loci for Servomechanism Components and Systems, Graphical. Thomas, Easton.....307–14; disc. 314
Determining Generator Reserve, A Convenient Method for. Seelye.....1317–20
Determining Incremental Regulation and Dead Band of Governors on Steam Turbine Generators Under System Load Conditions. Tornquist, Wade.....1343–7
Determining the Effects of Contaminants on Electrical Insulation, Methods for. Mathes, Sieffert, Walker, Lindsey.....113–18; disc. 118
Development and Application of Electric Heating to Deicing of Aircraft Propellers. Sheets, Sand..1068–72
Developments, Electronic Relay. Loving.....233–40; disc. 240
(Devices) A New Fourier Coefficient Harmonic Analyzer. Charp.....644–9; disc. 649
(Devices) Comparison of Long-Time and Short-Time Analog Computers. Paschkis.....70–3
Devices, Performance Characteristics of Lightning Protective. (Committee Report).....1333–6
Diagnosis of Rectifier Ailments. Dortort....1298–1304
Die-Cast Rotors for Induction Motors. Packer.....253–60; disc. 260
Dielectric Loss at High Frequencies and Under Changing Temperature, The Measurement of. Whitehead, Rueggeberg.....520–4
Dielectric Strength of Oil with Variations of Pressure and Temperature. Hoover, Hixson.....1047–50
Diesel-Electric Locomotives in Railroad Service, Application Engineering on. Bevan.....125–31
Diesel-Electric Rig for Deep-Well Drilling, Performance of. Clark, Moore.....497–506
Diesel-Electric Switching Locomotives, Industrial Plants Prefer. Woods.....697–700
Differential Leakage of the Different Patterns of a Fractional Slot Winding. Liwschitz.....1129–31; disc. 1131
Differential Series Fields in the Parallel Operation of D-C Motors, Use of Cumulative and. Kimball.....1098–1100
Dip—with Suddenly Applied Loads on A-C Generators, A Semiempirical Approach to Voltage. Rosenberg.....160–6; disc. 166
D-C Adjustable Speed Motors, Limitations in Design of. Opel.....1095–8
D-C Amplifier Stabilized for Gain and for Zero, Wide-Band. Williams, Amey, McAdam.....811–15; disc. 815
D-C Controllable Reactors, Universal Curves for. Johnson, Merrell, Alley.....31–7; disc. 37
D-C Controlled Reactors with Resistive Load, Some Fundamentals of. Storm.....188–94; disc. 194
D-C Machine Performance, The Eccentric Pole Face—A Means to Better. Baker.....1107–10
D-C Machines and Its Effects on Radio Influence Voltage Generation, Commutation of. Motter.....491–5; disc. 495
D-C Machines, Temperature Rise Values for. Part I. (Committee Report).....206–12; disc. 212
D-C Machines, Temperature Rise Values for. Part II. (Committee Report).....1118–23; disc. 1123
D-C Motors and Generators, Solid Short Circuit of. Linville, Ward.....119–23; disc. 123
D-C Motors and Generators, Transient Characteristics of. McClinton, Brancato, Panoff.....1100–06
D-C Motors for Use in Automatic Control Systems, The Design of. Lebenbaum.....1089–94
D-C Motors, Stray Load Losses Measured in. (Committee Report).....219–23; disc. 223
D-C Motors, Use of Cumulative and Differential Series Fields in the Parallel Operation of. Kimball.....1098–1100
D-C Series Motors—Experimental Study of Speed-Torque Curves, Dynamic Braking Control of. Heumann.....560–4
Direct Lightning Strokes, Transmission Line Design and Performance Based on. Harder, Clayton.....439–46; disc. 447
Distance Relays During Faults and Power Swings, Graphical Method for Estimating the Performance of. Warrington.....608–20; disc. 620
Distinction Between Effective and Circuit Bandwidths, The. Kessler.....98–9
Distribution System, Lightning Investigation on a Rural. MacCarthy, Stann, Edge, McKinley.....428–37; disc. 437
Distribution System, Operation of a Ground-Fault Neutralizer on a Regulated. Tomlinson, Hunt.....1321–6; disc. 1326
Distribution System, Overcurrent Investigation on a Rural. Lincks, Edge, McKinley, Leh.....915–27; disc. 927
Distribution Systems, Short-Circuit Currents and Recovery Voltages on Rural. Eason, Johnson, Kalb, Peterson.....930–7; disc. 937
Distribution Systems, Voltage-Recovery Characteristics of. Witzke.....172–80; disc. 180
Distribution Transformer and Secondary Conductor Economics. Brady.....483–6; disc. 486
Division Multiplexing System, A Time. Boothroyd, Creamer.....92–7
(Domestic) The Heat Pump—Its Significance as a Potential Residential Electric Load. Bary.....1–8
Drilling, Performance of Diesel-Electric Rig for Deep-Well. Clark, Moore.....497–506
Drive, A Wide-Range Adjustable-Speed. Conrad, Tribken.....789–90
Drives for Looms, Selection of Electric. Demartini, Lukens.....349–56
Duct Bank, The Temperature Rise of Cables in a. Neher.....540–6; disc. 546
Duquesne Light Company System, Primary Networks on the. Holben, Lange.....704–09; disc. 709
Dust in Rooms, Electrically Charged. Penney, Hewitt.....278–82
Dynamic Braking Control of D-C Series Motors—Experimental Study of Speed-Torque Curves. Heumann.....560–4
Dynamoelectric Amplifier—Class A Operation, The. Saunders.....1368–73

E

Eccentric Pole-Face—A Means to Better D-C Machine Performance, The. Baker.....1107–10
Economic Loading of a Transformer System. Levine Smith.....733–8; disc. 738
Economics, Distribution Transformer and Secondary Conductor. Brady.....483–6; disc. 486
Effect of Leakage Reactance, Saturation. Chang, Lloyd.....1144–7
Effective and Circuit Bandwidths, The Distinction Between. Kessler.....98–9
Effects of Commutator Surface Film Conditions on Commutation. Lynn, Elsey.....106–12; disc. 112
Effects of Contaminants on Electrical Insulation, Methods for Determining the. Mathes, Sieffert, Walker, Lindsey.....113–18; disc. 118
Electric Analog Computer to Nonlinear Mechanics and Servomechanisms, Application of the California Institute of Technology. McCann, Wilts, Locanthi.....652–60

Electric Brushes, Progress Report on AIEE Test Code for. (Committee Report)........1126–8
Electric Deicing System for Aircraft, An. Giloy........1051–7
Electric Drives for Looms, Selection of. Demartini, Lukens........349–56
Electric Equipment for Chesapeake and Ohio Railway Company Steam Turbine-Electric Locomotives. Atwell, Baston........145–8
(Electric Heating) The Measurement of Dielectric Loss at High Frequencies and Under Changing Temperature. Whitehead, Rueggeberg........520–4
Electric Heating to Deicing of Aircraft Propellers, Development and Application of. Sheets, Sand........1068–72
Electric Load, The Heat Pump—Its Significance as a Potential Residential. Bary........1–8
Electric Locomotives in Railroad Service, Application Engineering on Diesel-. Bevan........125–31
Electric Motive Power, The Renaissance of. Candee........138–44
Electric Power System, Transformer Audio Noise Problems on an. Murray........740–7; disc. 747
Electric Rig for Deep-Well Drilling, Performance of Diesel-. Clark, Moore........497–506
Electrical Analogy, The Transient Behavior of the Two-Stage Rototrol Main Exciter Voltage Regulating System as Determined by. Carleton........59–63
Electrical Characteristics of McNary Generators and Transformers with Bonneville Power Administration Transmission System, Matching. Hoard, Weiner........1022–5; disc. 1026
Electrical Design Features—Steam-Electric Generating Station P of the Pacific Gas and Electric Company. Benson........1013–20; disc. 1020
Electrical Insulation, Methods for Determining the Effects of Contaminants on. Mathes, Sieffert, Walker, Lindsey........113–11; disc. 118
Electrically Charged Dust in Rooms. Penney, Hewitt........278–82
(Electronic Instruments) A Square-Law Power-Level Recorder. Clark, Turner, Williams........476–82
(Electronic Power Converters) Diagnosis of Rectifier Ailments. Dortort........1298–1304
(Electronic Power Converters) Rectifier Fault Currents—II. Herskind, Schmidt, Rettig..243–51; disc. 251
(Electronic Power Converters) Rectifier Transformer Characteristics. (Committee Report)....1305–11
Electronic Relay Developments Loving........233–40; disc. 240
(Electronics) Analytical Determination of Characteristics of Magnetic Amplifiers with Feedback. VerPlanck, Finzi, Beaumariage........565–70
(Electronics) Electrically Charged Dust in Rooms. Penney, Hewitt........278–82
(Electronics) Heating of Radio-Frequency Cables. Macalpine........283–8
(Electronics) The Power Rating of Radio-Frequency Cables. Mildner........289–98; disc. 298
Electro-Optical Shutter for Photographic Purposes, An. Zarem, Marshall, Poole........84–91
Endurance of Class H Insulation and Silicone Varnish, Motor Tests Evaluate Thermal. Grant, Kauppi, Moses, Gibson........1133–8
Energy, Measurements of Erythemal. Scott....725–29
Engineering on Diesel-Electric Locomotives in Railroad Service, Application. Bevan........125–31
Equalization of Coaxial Lines. Gould........1187–92
Equalizers for Coaxial Lines, Attenuation and Delay. Lundry........1174–9
Equipment, A Proposal for Broad-Band Coupling of Power-Line Carrier. Miller...1028–30; disc. 1030
Equipment for Chesapeake and Ohio Railway Company Steam Turbine-Electric Locomotives, Electric. Atwell, Baston........145–8
Equipment for Land-Mobile Services Operating on Frequencies Between 152–174 Megacycles, Design of Mobile Radio Communication. Beers, Harris, Zappacosta........1232–9
Equipment, One Slip Cycle Out-of-Step Relay. Morris........1246–8
Equipment, Reduction of Interference from Radio-Frequency Heating. Klingaman..718–24; disc. 724
Equipment Used With Coaxial Cable for Carrier Current Installation on Power Lines, Line Tuning. Sutton........44–8; disc. 48
Equivalent Circuits for Power-Flow Studies. Ward........373–80; disc. 380
Erythemal Energy, Measurements of. Scott....725–29
Evaluate Thermal Endurance of Class H Insulation and Silicone Varnish, Motor Tests. Grant, Kauppi, Moses, Gibson........1133–8
Evaluation of the Stability of the Welding Arc, Instrumentation for the. Winsor, Schetky, Wyant........525–38
Excitation Relay for Synchronous Generators, A New Loss-of-. Mason........1240–5
Exciter Voltage Regulating System as Determined by Electrical Analogy, The Transient Behavior of the Two-Stage Rototrol Main. Carleton........59–63
Expanded Scale A-C Voltmeter, A New, Millar..641–3
Experience With 4-Kv Primary Network Systems in the Washington Area, Design and. Lank........712–16; disc. 716
Experimental Confirmation of the Moving Coil Fluxmeter, General Theory and. Higgins, Robertson........897–907; disc. 907
Experimental Study of Speed-Torque Curves, Dynamic Braking Control of D-C Series Motors—. Heumann........560–4
Experimental Test Procedures and Methods of Analysis of Results to Research Problems in Magnetic Recording, Application of. Thompson........407–17
Extremes in the Insulation Co-ordination of Oil Insulated Transformers. Vogel........965–8; disc. 968

F

Face—A Means to Better D-C Machine Performance, The Eccentric Pole. Baker........1107–10
Facsimile Transmission Speed, Considerations on. Burkhard........418–23; disc. 423
Factor of Unbalanced Sinusoidal 3-Phase Circuits, The Vector Power. Lamb, Brandt........507–09
Fault-Arc Paths, Deionization Time of High-Voltage. Harrington, Starr........997–1003; disc. 1003
Fault Currents, Rectifier—II. Herskind, Schmidt, Rettig........243–51; disc. 251
Fault Limiting Means on High Interrupting Capacity Controllers, The Use of Air-Core Reactors as. Leitch........469–74; disc. 474
Fault Locator for High-Voltage Transmission Lines, A Transient. Spaulding, Diemond........1005–1010; disc. 1010
Fault Neutralizer on a Regulated Distribution System, Operation of a Ground-. Tomlinson, Hunt........1321–6; disc. 1326
Fault Neutralizers, Report on Survey of Unbalanced Charging Currents on Transmission Lines as Affecting Ground-. (Committee Report)........1328; disc. 1329
Faults and Power Swings, Graphical Method for Estimating the Performance of Distance Relays During. Warrington........608–20; disc. 620
Features—Steam-Electric Generating Station P of the Pacific Gas and Electric Company, Electrical Design. Benson........1013–20; disc. 1020
Feedback, Analytical Determination of Characteristics of Magnetic Amplifiers with. VerPlanck, Finzi, Beaumariage........565–70
Feed-Back Control Systems with Particular Reference to Backlash, Instrument Inaccuracies in. Marcy, Yachter, Zauderer........778–88
Field Components of Circular Filaments and Solenoids, Formulas and Tables for the Calculation of the Magnetic. Grover........665–75
Field Fluxes of the Shaded-Pole Motor, The. Kimberly........273–7
Field Tests of Oil Circuit Recloser Substantiate Analytical Co-ordination Method. Auer, Branflick, Woodward, McKinley........801–08; disc. 808
Fields in the Parallel Operation of D-C Motors, Use of Cumulative and Differential Series. Kimball........1098–1100
Filaments and Solenoids, Formulas and Tables for the Calculation of the Magnetic Field Components of Circular. Grover........665–75
Film Conditions on Commutation, Effects of Commutator Surface. Lynn, Elsey...106–12; disc. 112
Flashover Deionization Times as a Factor in Applying High-Speed Reclosing Circuit Breakers, Insulator. Boisseau, Wyman, Skeats........1058–66; disc. 1066
Flow Ratio as a Design Parameter in Thermal Demand Meters, Heat. Nelson........885–90; disc. 890
Fluxes of the Shaded-Pole Motor, The Field. Kimberly........273–7
Fluxmeter, General Theory and Experimental Confirmation of the Moving Coil. Higgins, Robertson........897–907; disc. 907
Formulas and Tables for the Calculation of the Magnetic Field Components of Circular Filaments and Solenoids. Grover........665–75
Fourier Coefficient Harmonic Analyzer, A New. Charp........644–9; disc. 649
Fractional Slot Winding, Differential Leakage of the Different Patterns of a. Liwschitz........1129–31; disc. 1131
Frames, Stationary Networks and Transmission Lines Along Uniformly Rotating Reference. Kron........690–6
Frequencies and Under Changing Temperature, The Measurement of Dielectric Loss at High. Whitehead, Rueggeberg........520–4
Frequencies, Loss Measurements Made on Underground-Cable Overhead-Conductor 132-Kv Transmission Line at Carrier Current. Cornelius, Storer........597–601
Frequency Cables, Heating of Radio-. Macalpine........283–8
Frequency Cables, The Power Rating of Radio-Mildner........289–98; disc. 298
Frequency Heating Equipment, Reduction of Interference from Radio-. Klingman..718–24; disc. 724
Frequency Response Curves, Control Chart Methods Applied to. Mundel........424–7
Fuel Cost and Transmission Loss by Use of the Network Analyzer to Determine Plant Loading Schedules, Co-ordination of. George, Page, Ward........1152–60; disc. 1160
Function Loci for Servomechanism Components and Systems, Graphical Determination of Transfer. Thomas, Easton........307–14; disc. 314
Functions of Schwartz, A Derivation of Heaviside's Operational Calculus Based on the Generalized. Smith, Alger........939–44; disc. 944
Fundamental Theory of Inherent-Overheating Protection Under Running Overload Conditions. Veinott, Schaefer........266–70; disc. 270
Fundamentals, and Design Improvements, Aircraft Carbon-Pile Voltage Regulators. Austin, Richards........983–7
Fundamentals of D-C Controlled Reactors with Resistive Load, Some. Storm.....188–94; disc. 194
Fundamentals of Potheads 69,000 Volts and Below Design. Nicholas........1263–7; disc. 1267
Fuses, The Calculated Risk of Operating Capacitors Without Individual. Brooks...1219–25; disc. 1225

G

Gain and for Zero, Wide-Band D-C Amplifier Stabilized for. Williams, Amey, McAdam..811–15; disc. 815
Gas-Filled Cable Impregnated with Extra-High-Viscosity Oil, High-Pressure. Sticher, Doan, Atkinson, Meyerhoff........336–45; disc. 345
Gas Turbine Power Plant, A 3,000-Horsepower. Haverstick........458–60
Gas Turbines for Power Generation and Other Applications, Two. Howard........461–5; disc. 465
Gas Turbines in Stationary Power Generation. Hague........467–8
General Theory and Experimental Confirmation of the Moving Coil Fluxmeter. Higgins, Robertson........897–907; disc. 907
General Theory of Multiple Cage Induction Motors. Chang........1139–43
Generating Station P of the Pacific Gas and Electric Company, Electrical Design Features—Steam-Electric. Benson........1013–20; disc. 1020
Generating Station, Relaying of Transmission Lines from the New. Green, Oewel, Ramsaur........873–7; disc. 877
Generation and Other Applications, Two Gas Turbines for Power. Howard........461–5; disc. 465
Generation, Commutation of D-C Machines and Its Effects on Radio Influence Voltage. Motter........491–5; disc. 495
Generation, Gas Turbines in Stationary Power. Hague........467–8
Generator Reserve, A Convenient Method for Determining. Seelye........1317–20
Generators, A New Automatic Load Control for Turbine. Ruud, Farnham........1337–42; disc. 1342
Generators, A New Loss-of-Excitation Relay for Synchronous. Mason........1240–5
Generators, A Semiempirical Approach to Voltage Dip—with Suddenly Applied Loads on A-C. Rosenberg........160–6; disc. 166
Generators and Transformers with Bonneville Power Administration Transmission System, Matching Electrical Characteristics of McNary. Hoard, Weiner........1022–5; disc. 1026
Generators, Solid Short Circuit of D-C Motors and. Linville, Ward........119–23; disc. 123
Generators, Transient Characteristics of D-C Motors and. McClinton, Brancato, Panoff......1100–06
Generators Under System Load Conditions, Determining Incremental Regulation and Dead Band of Governors on Steam Turbine. Tornquist, Wade........1343–7
Geometric Loci of the Synchronous Tie, The. Finzi, Wellard........168–71
Governors and the AIEE-ASME Governor Performance Specification. Schwendner, Astley........1330–2
Governors on Steam Turbine Generators Under System Load Conditions, Determining Incremental Regulation and Dead Band of. Tornquist, Wade........1343–7
Graphical Determination of Transfer Function Loci for Servomechanism Components and Systems. Thomas, Easton........307–14; disc. 314
Graphical Method for Estimating the Performance of Distance Relays During Faults and Power Swings. Warrington........608–20; disc. 620
Ground-Fault Neutralizer on a Regulated Distribution System, Operation of a. Tomlinson, Hunt........1321–6; disc. 1326
Ground-Fault Neutralizers, Report on Survey of Unbalanced Charging Currents on Transmission Lines as Affecting. (Committee Report)........1328; disc. 1329

Grounding and Air-Break Switches for Protection of Transformer Stations, Automatic. Ricker........851–6; disc. 856

H

Harmonic Analyzer, A New Fourier Coefficient. Charp........644–9; disc. 649
Heat Flow Ratio as a Design Parameter in Thermal Demand Meters. Nelson........885–90; disc. 890
Heat Pump—Its Significance as a Potential Residential Electric Load, The. Bary........1–8
Heat Run Data, Prediction of Ultimate Temperature Rise from Early. Ryan........1164–6
Heating Equipment, Reduction of Interference from Radio-Frequency. Klingaman..718–24; disc. 724
Heating of Radio-Frequency Cables. Macalpine..283–8
Heating of Transformers Under Short-Circuit Conditions. Montsinger, Halsey........947–52; disc. 952
Heating of Transmission Line Clamps, Magnetic. Crabb, Sheadel........1032–5
Heating to Deicing of Aircraft Propellers, Development and Application of Electric. Sheets, Sand..1068–72
Heaviside's Operational Calculus Based on the Generalized Functions of Schwartz, A Derivation of. Smith, Alger........939–44; disc. 944
High Frequencies and Under Changing Temperature, The Measurement of Dielectric Loss at. Whitehead, Rueggeberg........520–4
High-Pressure Gas-Filled Cable Impregnated with Extra-High-Viscosity Oil. Sticher, Doan, Atkinson, Meyerhoff........336–45; disc. 345
High-Speed Reclosing Circuit Breakers, Insulator Flashover Deionization Times as a Factor in Applying. Boisseau, Wyman, Skeats........1058–66; disc. 1066
High-Voltage Bushing Design for High Altitudes, A Small. Vogel, Hart........761–4
High-Voltage Cable Joints, A Theoretical and Practical Approach to the Design of. Short........1275–80; disc. 1280
High-Voltage Corona, Radio Influence from. Slemon........198–204; disc. 204
High-Voltage Fault-Arc Paths, Deionization Time of. Harrington, Starr........997–1003; disc. 1003
High-Voltage Switching, Protection of Stations Without. (Committee Report)........226–31; disc. 231
High-Voltage Transmission Lines, A Transient Fault Locator for. Spaulding, Diemond........1005–1010; disc. 1010
Horsepower Gas Turbine Power Plant, A 3,000-. Haverstick........458–60
Hydraulic Conditions During Operation of Hydroelectric Units, Some Oscillographic Methods of Investigating Mechanical and. Engvall....993–6
Hydro Units, Outage Rates of Steam Turbines and Boilers and of. (Committee Report)........450–7
Hydroelectric Units, Some Oscillographic Methods of Investigating Mechanical and Hydraulic Conditions During Operation of. Engvall........993–6
Hy-Therm Copper—An Improved Overhead-Line Conductor. Hickernell, Jones, Snyder........22–7; disc. 27

I

Impregnated with Extra-High-Viscosity Oil, High-Pressure Gas-Filled Cable. Sticher, Doan, Atkinson, Meyerhoff........336–45; disc. 345
Improved A-C Network Analyzer, An. Morgan, Rothe, Winsness........891–5; disc. 895
Improvements, Aircraft Carbon-Pile Voltage Regulators, Fundamentals, and Design. Austin, Richards........983–7
Improvements to Oklahoma City Primary Network. Brady........701–02; disc. 702
Incandescent Lamps, Saving Time in Testing Life of. Purcell........730–2
Incremental Regulation and Dead Band of Governors on Steam Turbine Generators Under System Load Conditions, Determining. Tornquist, Wade........1343–7
Indicating Instrument, Measuring Commutation with an. Lundy........1380–2
Indicator, Polar Vector. Walker, Waynick, Sulzer........154–9
Induction Motors, Die-Cast Rotors for. Packer........253–60; disc. 260
Induction Motors, Design of Auxiliary Circuits of Single-Phase. Thacker, Gopalakrishna....1373–9
Induction Motors, General Theory of Multiple Cage. Chang........1139–43
(Industrial Control) Prediction of Ultimate Temperature Rise from Early Heat Run Data. Ryan...1164–6
(Industrial Control) The Use of Air-Core Reactors as Fault Limiting Means on High Interrupting Capacity Controllers. Leitch.....469–74; disc. 474
(Industrial) Dynamic Braking Control of D-C Series Motors—Experimental Study of Speed-Torque Curves. Heumann........560–4
Industrial Plants Prefer Diesel-Electric Switching Locomotives. Woods........697–700
(Industry) Selection of Electric Drives for Looms. Demartini, Lukens........349–56
Influence from High-Voltage Corona, Radio. Slemon........198–204; disc. 204
Influence Voltage Generation, Commutation of D-C Machines and Its Effects on Radio. Motter........491–5; disc. 495
Inherent-Overheating Protection Under Running Overload Conditions, Fundamental Theory of. Veinott, Schaefer........266–70; disc. 270
Installation on Power Lines, Line Tuning Equipment Used With Coaxial Cable for Carrier Current. Sutton........44–8; disc. 48
Instrument Inaccuracies in Feed-Back Control Systems with Particular Reference to Backlash. Marcy, Yachter, Zauderer........778–88
Instrument, Measuring Commutation with an Indicating. Lundy........1380–2
Instrument Servomechanisms, Damper Stabilized. Hall........299–306; disc. 306
Instrumentation for the Evaluation of the Stability of the Welding Arc. Winsor, Schetky, Wyant........525–33
(Instruments) A New Expanded Scale A-C Voltmeter. Millar........641–3
(Instruments) A New Thermal Volt-Ampere Demand Meter. Douglass, Morong........79–83; disc. 83
(Instruments) A Transient Fault Locator for High-Voltage Transmission Lines. Spaulding, Demond........1005–10; disc. 1010
(Instruments) An Electro-Optical Shutter for Photographic Purposes. Zarem, Marshall, Poole..84–91

(Instruments) Polar Vector Indicator. Walker, Waynick, Sulzer........154–9
(Instruments) Surge Protection in a Modern Watt-Hour Meter. Busch, Williams........74–7; disc. 77
(Insulated Conductors) A-C Resistance of Segmental Cables in Steel Pipe. Meyerhoff, Eager........816–29; disc. 829
(Insulated Conductors) High-Pressure Gas-Filled Cable Impregnated with Extra-High-Viscosity Oil. Sticher, Doan, Atkinson, Meyerhoff........336–45; disc. 345
(Insulated Conductors) The Thermal Movement of Moisture in Soil. Mickley........330–3; disc. 333
(Insulated Conductors) Transformer Manholes and Vaults: Design and Ventilation. Porter....534–9
Insulation and Silicone Varnish, Motor Tests Evaluate Thermal Endurance of Class-H. Grant, Kauppi, Moses, Gibson........1133–8
Insulation Co-ordination of Oil Insulated Transformers, Extremes in the. Vogel........965–8; disc. 968
Insulation Level of Relay and Control Circuits. (Committee Report)........1255–7
Insulation, Methods for Determining the Effects of Contaminants on Electrical. Mathes, Sieffert, Walker, Lindsey........113–18; disc. 118
Insulation Protection in the Operation of Power Transformers, Controlled Temperature and. Satterlee, Reed........753–8; disc. 759
Insulator Flashover Deionization Times as a Factor in Applying High-Speed Reclosing Circuit Breakers. Boisseau, Wyman, Skeats........1058–66; disc. 1066
Insulators for Pole Lines, Rubber. Wheeler, Markley........195–7
Interference from Radio-Frequency Heating Equipment, Reduction of. Klingaman........718–24; disc. 724
Interrupting Capacity Controllers, The Use of Air-Core Reactors as Fault Limiting Means on High-. Leitch........469–74; disc. 474
Investigating Mechanical and Hydraulic Conditions During Operation of Hydroelectric Units, Some Oscillographic Methods of. Engvall........993–6
Investigation on a Rural Distribution System, Lightning. MacCarthy, Stann, Edge, McKinley........428–37; disc. 437
Investigation on a Rural Distribution System, Overcurrent. Lincks, Edge, McKinley, Leh........915–27; disc. 927
Iron Losses in Series Motors, Armature. Chang, Karr........262–4; disc. 264

J

Joint Usage, Power Line Carrier for Relaying and. Part I. Hampe, Storer........864–7; disc. 871
Joints, A Theoretical and Practical Approach to the Design of High-Voltage Cable. Short........1275–80; disc. 1280
Joints by Means of a Bolometer, Detection of Overheated Transmission Line. Leslie, Wait....64–8; disc. 68

L

Laboratory Techniques, Cable Accessory Design Utilizing New. Bosworth, Farr.....1268–73; disc. 1273
Lamps, Saving Time in Testing Life of Incandescent. Purcell........730–2
Land-Mobile Services Operating on Frequencies Between 152–174 Megacycles, Design of Mobile Radio Communication Equipment for. Beers, Harris, Zappacosta........1232–9
(Land Transportation) Application Engineering on Diesel-Electric Locomotives in Railroad Service. Bevan........125–31
(Land Transportation) Electric Equipment for Chesapeake and Ohio Railway Company Steam Turbine-Electric Locomotives. Atwell, Baston........145–8
(Land Transportation) Industrial Plants Prefer Diesel-Electric Switching Locomotives. Woods..697–700
(Land Transportation) Selenium Rectifiers in Motor Vehicle Power Systems. Ramsey..149–53; disc. 153
(Land Transportation) The Renaissance of Electric Motive Power. Candee........138–44
(Land Transportation) Trackless Trolley Operation in Rhode Island. Blomquist........397–402
(Land Transportation) Trolley Coaches Replace Busses. McMillon........403–06
(Land Transportation) Twenty-Five Years Progress in the Design of Traction Motors. Baldwin....132–7
Law Power-Level Recorder, A Square. Clark, Turner, Williams........476–82
Leakage of the Different Patterns of a Fractional Slot Winding, Differential. Liwschitz........1129–31; disc. 1131
Leakage Reactance, Saturation Effect of. Chang, Lloyd........1144–7
Level of Relay and Control Circuits, Insulation. (Committee Report)........1255–7
Level Recorder, A Square-Law Power-. Clark, Turner, Williams........476–82
Life of Incandescent Lamps, Saving Time in Testing. Purcell........730–2
(Light) Measurements of Erythemal Energy. Scott........725–9
(Light) Saving Time in Testing Life of Incandescent Lamps. Purcell........730–2
Lightning Investigation on a Rural Distribution System. MacCarthy, Stann, Edge, McKinley........428–37; disc. 437
Lightning Measurements, Advances in Technique of. Brownlee........515–19
Lightning Protective Devices, Performance Characteristics of. (Committee Report)........1333–6
Lightning Stroke Damage to Aircraft. Hagenguth........1036–44; disc. 1044
Lightning Strokes, Transmission Line Design and Performance Based on Direct. Harder, Clayton........439–46; disc. 447
Lightweight Aircraft Transformers. Stephens...1073–8
Limitations in Design of D-C Adjustable Speed Motors. Opel........1095–8
Limiting Means on High Interrupting Capacity Controllers, The Use of Air-Core Reactors as Fault. Leitch........469–74; disc. 474
Line at Carrier Current Frequencies, Loss Measurements Made on Underground-Cable Overhead-Conductor 132-Kv Transmission. Cornelius, Storer..597–601
Line Carrier Equipment, A Proposal for Broad-Band Coupling of Power-. Miller...1028–30; disc. 1030
Line Carrier for Relaying and Joint Usage, Power, Part I. Hampe, Storer........864–7; disc. 871
Line Clamps, Magnetic Heating of Transmission. Crabb, Sheadel........1032–5
Line Conductor, Hy-Therm Copper—An Improved Overhead-. Hickernell, Jones, Snyder........22–7; disc. 27
Line Design and Performance Based on Direct Lightning Strokes, Transmission. Harder, Clayton........439–46; disc. 447
Line Joints by Means of a Bolometer, Detection of Overheated Transmission. Leslie, Wait........64–8; disc. 68
Line Sectionalizing Circuit Breakers, A-C Tripping and Reclosing of. Winegartner, Bonheimer....1357–9
Line Tuning Equipment Used With Coaxial Cable for Carrier Current Installation on Power Lines. Sutton........44–8; disc. 48
Linear Vibration Problems, Summary of Transformations Useful in Constructing Analogs of. Corbett........661–4
Lines, A Transient Fault Locator for High-Voltage Transmission. Spaulding, Diemond........1005–10; disc. 1010
Lines Along Uniformly Rotating Reference Frames, Stationary Networks and Transmission. Kron........690–6
Lines as Affecting Ground-Fault Neutralizers, Report on Survey of Unbalanced Charging Currents on Transmission. (Committee Report)....1328; disc. 1329
Lines, Attenuation and Delay Equalizers for Coaxial. Lundry........1174–9
Lines, Comparative Performance Records—Steel and Wood Transmission. Booker.....686–9; disc. 689
Lines, Equalization of Coaxial. Gould........1187–92
Lines from the New Sunbury Generating Station, Relaying of Transmission. Green, Oewel, Ramsaur........873–7; disc. 877
Lines, Rubber Insulators for Pole. Wheeler, Markley........195–7

Load Conditions, Determining Incremental Regulation and Dead Band of Governors on Steam Turbine Generators Under System. Tornquist, Wade..........1343–7

Load Control for Turbine Generators, A New Automatic. Ruud, Farnham..........1337–42; disc. 1342

Load Losses Measured in D-C Motors, Stray. (Committee Report)..........219–23; disc. 223

Load Reduction, The Performance of a Topped Steam Power Plant on Sudden. Noest..........1348–56

Load, Some Fundamentals of D-C Controlled Reactors with Resistive. Storm..........188–94; disc. 194

Load, The Heat Pump—Its Significance as a Potential Residential Electric. Bary..........1–8

Loading of a Transformer System, Economic. Levine, Smith..........733–8; disc. 738

Loading Schedules, Co-ordination of Fuel Cost and Transmission Loss by Use of the Network Analyzer to Determine Plant. George, Page, Ward..........1152–60; disc. 1160

Loads on A-C Generators, A Semiempirical Approach to Voltage Dip—with Suddenly Applied. Rosenberg..........160–6; disc. 166

Locator for High-Voltage Transmission Lines, A Transient Fault. Spaulding, Diemond..........1005–1010; disc. 1010

Loci for Servomechanism Components and Systems, Graphical Determination of Transfer Function. Thomas, Easton..........307–14; disc. 314

Loci of the Synchronous Tie, The Geometric. Finzi, Wellard..........168–71

Locomotives, Electric Equipment for Chesapeake and Ohio Railway Company Steam Turbine-Electric. Atwell, Baston..........145–8

Locomotives in Railroad Service, Application Engineering on Diesel-Electric. Bevan..........125–31

Locomotives, Industrial Plants Prefer Diesel-Electric Switching. Woods..........697–700

Logic of Relay Circuits, The. Keister..........571–6

Long-Time and Short-Time Analog Computers, Comparison of. Paschkis..........70–3

Loss at High Frequencies and Under Changing Temperature, The Measurement of Dielectric. Whitehead, Rueggeberg..........520–4

Loss by Use of the Network Analyzer to Determine Plant Loading Schedules, Co-ordination of Fuel Cost and Transmission. George, Page, Ward..........1152–60; disc. 1160

Loss Measurements Made on Underground-Cable Overhead-Conductor 132-Kv Transmission Line at Carrier Current Frequencies. Cornelius, Storer..........597–601

Loss-of-Excitation Relay for Synchronous Generators, A New. Mason..........1240–5

Losses in Series Motors, Armature Iron. Chang, Karr..........262–4; disc. 264

Losses Measured in D-C Motors, Stray Load. (Committee Report)..........219–23; disc. 223

M

Machine Performance, The Eccentric Pole Face—A Means to Better D-C. Baker..........1107–10

Machine, The Negative-Sequence Reactances of an Ideal Synchronous. Duesterhoeft..........510–13; disc. 513

Machines and Its Effects on Radio Influence Voltage Generation, Commutation of D-C. Motter..........491–5; disc. 495

Machines, Temperature Rise Values for D-C. Part I. (Committee Report)..........206–12; disc. 212

Machines, Temperature Rise Values for D-C. Part II. (Committee Report)..........1118–23; disc. 1123

Machines, Transients in 2-Phase Synchronous. Wilson..........1360–7

Magnetic Amplifiers, Self-Saturation in. Dornhoefer..........835–46; disc. 846

Magnetic Amplifiers with Feedback, Analytical Determination of Characteristics of. VerPlanck, Finzi, Beaumariage..........565–70

Magnetic Field Components of Circular Filaments and Solenoids, Formulas and Tables for the Calculation of the. Grover..........665–75

Magnetic Heating of Transmission Line Clamps. Crabb, Sheadel..........1032–5

Magnetic Recording, Application of Experimental Test Procedures and Methods of Analysis of Results to Research Problems in. Thompson..........407–17

Magnetic Saturation, Nonharmonic Oscillations as Caused by. Rudenberg..........676–85

Main Bus, Protection of the Airplane. Exner..........979–82

Maintenance of Shunt Capacitors, Report on the Operation and. (Committee Report)..........1208–18

Manholes and Vaults: Design and Ventilation, Transformer. Porter..........534–9

Manually-Operated Spring Mechanism for Medium Voltage Oilless Circuit Breakers, A. Wyman, Casey..........357–61; disc. 361

Manufacture of Soldered Porcelain Potheads, A New Technique in the. Papp, Nicholas..........1258–60; disc. 1261

Matching Electrical Characteristics of McNary Generators and Transformers with Bonneville Power Administration Transmission System. Hoard, Weiner..........1022–5; disc. 1026

McNary Generators and Transformers with Bonneville Power Administration Transmission System, Matching Electrical Characteristics of. Hoard, Weiner..........1022–5; disc. 1026

Means on High Interrupting Capacity Controllers, The Use of Air-Core Reactors as Fault Limiting. Leitch..........469–74; disc. 474

Measurement of Dielectric Loss at High Frequencies and Under Changing Temperature, The. Whitehead, Rueggeberg..........520–4

Measurements, Advances in Technique of Lightning. Brownlee..........515–19

Measurements Made on Underground-Cable Overhead-Conductor 132-Kv Transmission Line at Carrier Current Frequencies, Loss. Cornelius, Storer..........597–601

Measurements of Erythemal Energy. Scott..........725–29

Measuring Commutation with an Indicating Instrument Lundy..........1380–2

Mechanical and Hydraulic Conditions During Operation of Hydroelectric Units, Some Oscillographic Methods of Investigating. Engvall..........993–6

Mechanics and Servomechanisms, Application of the California Institute of Technology Electric Analog Computer to Nonlinear. McCann, Wilts, Locanthi..........652–60

Mechanism for Medium Voltage Oilless Circuit Breakers, A Manually-Operated Spring. Wyman, Casey..........357–61; disc. 361

Megacycles, Design of Mobile Radio Communication Equipment for Land-Mobile Services Operating on Frequencies Between 152–174. Beers, Harris, Zappacosta..........1232–9

Meter, A New Thermal Volt-Ampere Demand. Douglass, Morong..........79–83; disc. 83

Meter, Surge Protection in a Modern Watt-Hour. Busch, Williams..........74–7; disc. 77

Meters, Heat Flow Ratio as a Design Parameter in Thermal Demand. Nelson..........885–90; disc. 890

Method, Field Tests of Oil Circuit Recloser Substantiate Analytical Co-ordination. Auer, Branflick, Woodward, McKinley..........801–08; disc. 808

Method for Designing Pulse Transformers, A. Kirschbaum, Warren..........971–8

Method for Determining Generator Reserve, A Convenient. Seelye..........1317–20

Method for Estimating the Performance of Distance Relays During Faults and Power Swings, Graphical. Warrington..........608–20; disc. 620

Methods Applied to Frequency Response Curves, Control Chart. Mundel..........424–7

Methods for Determining the Effects of Contaminants on Electrical Insulation. Mathes, Sieffert, Walker, Lindsey..........113–18; disc. 118

Methods of Analysis of Results to Research Problems in Magnetic Recording, Application of Experimental Test Procedures and. Thompson..........407–17

Methods of Investigating Mechanical and Hydraulic Conditions During Operation of Hydroelectric Units, Some Oscillographic. Engvall..........993–6

Metropolitan Area, A 66-Kv Subtransmission Plan for a. Smith, Michelson..........908–12; disc. 912

Microwave Channels for Power System Applications. (Committee Report)..........40–2; disc. 42

Microwave Communication Relay System, A. Boothroyd, Churchill..........637–41

Microwave Relay Systems, Power Supplies for. Ward..........631–6

Mobile Radio Communication Equipment for Land-Mobile Services Operating on Frequencies Between 152–174 Megacycles, Design of. Beers, Harris, Zappacosta..........1232–9

Mobile Radio Systems, Vibrating Reed Selectors for. Keller, Bostwick..........383–6

Mobile Telephone Use, Vibrating Reed Selective Signaling System for. Pruden, Hoth..........387–91

Modern Watt-Hour Meter, Surge Protection in a. Busch, Williams..........74–7; disc. 77

Moisture in Soil, The Thermal Movement of. Mickley..........330–3; disc. 333

Motive Power, The Renaissance of Electric. Candee..........138–44

Motor Tests Evaluate Thermal Endurance of Class-H Insulation and Silicone Varnish. Grant, Kauppi, Moses, Gibson..........1133–8

Motor, The Field Fluxes of the Shaded-Pole. Kimberly..........273–7

Motor Vehicle Power Systems, Selenium Rectifiers in. Ramsey..........149–53; disc. 153

Motors and Generators, Solid Short Circuit of D-C. Linville, Ward..........119–23; disc. 123

Motors and Generators, Transient Characteristics of D-C. McClinton, Brancato, Panoff..........1100–06

Motors, Armature Iron Losses in Series. Chang, Karr..........262–4; disc. 264

Motors, Design of Auxiliary Circuits of Single-Phase Induction. Thacker, Gopalakrishna..........1373–9

Motors, Die-Cast Rotors for Induction. Packer..........253–60; disc. 260

Motors—Experimental Study of Speed-Torque Curves, Dynamic Braking Control of D-C Series. Heumann..........560–4

Motors for Use in Automatic Control Systems, The Design of D-C. Lebenbaum..........1089–94

Motors, General Theory of Multiple Cage Induction. Chang..........1139–43

Motors, Limitations in Design of D-C Adjustable Speed. Opel..........1095–8

Motors, Stray Load Losses Measured in D-C. (Committee Report)..........219–23; disc. 223

Motors, Twenty-Five Years Progress in the Design of Traction. Baldwin..........132–7

Motors, Use of Cumulative and Differential Series Fields in the Parallel Operation of D-C. Kimball..........1098–1100

Movement of Moisture in Soil, The Thermal. Mickley..........330–3; disc. 333

Moving Coil Fluxmeter, General Theory and Experimental Confirmation of the. Higgins, Robertson..........897–907; disc. 907

Multifrequency Pulsing in Switching, Application of. Dahlbom, Horton, Moody..........392–6

Multiple Cage Induction Motors, General Theory of. Chang..........1139–43

Multiplexing System, A Time Division. Boothroyd, Creamer..........92–7

N

Negative-Sequence Reactances of an Ideal Synchronous Machine, The. Duesterhoeft..........510–13; disc. 513

Network Analyzer, An Improved A-C. Morgan, Rothe, Winsness..........891–5; disc. 895

Network Analyzer to Determine Plant Loading Schedules, Co-ordination of Fuel Cost and Transmission Loss by Use of the. George, Page, Ward..........1152–60; disc. 1160

Network, Improvements to Oklahoma City Primary. Brady..........701–02; disc. 702

Network Systems in the Washington Area, Design and Experience With 4-Kv Primary. Lank..........712–16; disc. 716

Networks and Transmission Lines Along Uniformly Rotating Reference Frames. Kron..........690–6

Networks on the Duquesne Light Company System, Primary. Holben, Lange..........704–09; disc. 709

Neutralizer on a Regulated Distribution System, Operation of a Ground-Fault. Tomlinson, Hunt..........1321–6; disc. 1326

Neutralizers, Report on Survey of Unbalanced Charging Currents on Transmission Lines as Affecting Ground-Fault. (Committee Report)..........1328; disc. 1329

New Automatic Load Control for Turbine Generators, A. Ruud, Farnham..........1337–42; disc. 1342

New Expanded Scale A-C Voltmeter, A. Millar..........641–3

New Loss-of-Excitation Relay for Synchronous Generators, A. Mason..........1240–5

New 69-Kv Compressed-Air Circuit Breaker, A. Baker, Frisch..........363–8; disc. 369

Noise Problems on an Electric Power System, Transformer Audio. Murray..........740–7; disc. 747

Nonharmonic Oscillations as Caused by Magnetic Saturation. Rudenberg..........676–85

Nonlinear Mechanics and Servomechanisms, Application of the California Institute of Technology Electric Analog Computer to. McCann, Wilts, Locanthi..........652–60

Novel Test Circuits for Protective Relays. Sonnemann..........1249–54

O

Officers and Committees—1949–1950..........1409–28

Oil Circuit Recloser Substantiate Analytical Co-ordination Method, Field Tests of. Auer, Branflick, Woodward, McKinley..........801–08; disc. 808

Oil, High-Pressure Gas-Filled Cable Impregnated with Extra-High-Viscosity. Sticher, Doan, Atkinson, Meyerhoff..........336–45; disc. 345

Oil Insulated Transformers, Extremes in the Insulation Co-ordination of. Vogel..........965–8; disc. 968

Oil with Variations of Pressure and Temperature, Dielectric Strength of. Hoover, Hixson..........1047–50

Oilless Circuit Breakers, A Manually-Operated Spring Mechanism for Medium Voltage. Wyman, Casey..........357–61; disc. 361

Oklahoma City Primary Network, Improvements to. Brady..........701–02; disc. 702

One Slip Cycle Out-of-Step Relay Equipment. Morris..........1246–8

Operated Spring Mechanism for Medium Voltage Oilless Circuit Breakers, A Manually-. Wyman, Casey..........357–61; disc. 361

Operating Capacitors Without Individual Fuses, The Calculated Risk of. Brooks...1219–25; disc. 1225
Operating Characteristics of Two-Phase Servomotors. Koopman....319–27; disc. 327
Operation and Maintenance of Shunt Capacitors, Report on the. (Committee Report)....1208–18
Operation in Rhode Island, Trackless Trolley. Blomquist....397–402
Operation of a Ground-Fault Neutralizer on a Regulated Distribution System. Tomlinson, Hunt....1321–6; disc. 1326
Operation of D-C Motors, Use of Cumulative and Differential Series Fields in the Parallel. Kimball....1098–1100
Operation, The Dynamoelectric Amplifier—Class A. Saunders....1368–73
Operational Calculus Based on the Generalized Functions of Schwartz, A Derivation of Heaviside's Smith, Alger....939–44; disc. 944
Optical Shutter for Photographic Purposes, An Electro-. Zarem, Marshall, Poole....84–91
Oscillations as Caused by Magnetic Saturation, Nonharmonic. Rudenberg....676–85
Oscillographic Methods of Investigating Mechanical and Hydraulic Conditions During Operation of Hydroelectric Units. Engvall....93–6
Oscillographing Commutation. Baldwin....100–05; disc. 105
Outage Rates of Steam Turbines and Boilers and of Hydro Units. (Committee Report)....450–7
Overcurrent Investigation on a Rural Distribution System. Lincks, Edge, McKinley, Leh....915–27; disc. 927
Overhead-Conductor 132-Kv Transmission Line at Carrier Current Frequencies, Loss Measurements Made on Underground-Cable. Cornelius, Storer....597–601
Overhead-Line Conductor, Hy-Therm Copper—An Improved. Hickernell, Jones, Snyder....22–7; disc. 27
Overheated Transmission Line Joints by Means of a Bolometer, Detection of. Leslie, Wait....64–8; disc. 68
Overheating Protection Under Running Overload Conditions, Fundamental Theory of Inherent-. Veinott, Schaefer....266–70; disc. 270
Overload Conditions, Fundamental Theory of Inherent-Overheating Protection Under Running. Veinott, Schaefer....266–70; disc. 270

P

Pacific Gas and Electric Company, Electrical Design Features—Steam-Electric Generating Station P of the. Benson....1013–20; disc. 1020
Parallel Operation of D-C Motors, Use of Cumulative and Differential Series Fields in the. Kimball....1098–1100
Parameter in Thermal Demand Meters, Heat Flow Ratio as a Design. Nelson....885–90; disc. 890
Paths, Deionization Time of High-Voltage Fault-Arc. Harrington, Starr....997–1003; disc. 1003
Patterns of a Fractional Slot Winding, Differential Leakage of the Different. Liwschitz....1129–31; disc. 1131
Performance Based on Direct Lightning Strokes, Transmission Line Design and. Harder, Clayton....439–46; disc. 447
Performance Characteristics of Lightning Protective Devices. (Committee Report)....1333–6
Performance of a Topped Steam Power Plant on Sudden Load Reduction, The. Noest....1348–56
Performance of Diesel-Electric Rig for Deep-Well Drilling. Clark, Moore....497–506
Performance of Distance Relays During Faults and Power Swings, Graphical Method for Estimating the. Warrington....608–20; disc. 620
Performance of Servomechanisms, Comparison of Steady-State and Transient. Chestnut, Mayer....765–77
Performance of Shunt Capacitors, Report of a Survey on the. (Committee Report)....1200–06; disc. 1206
Performance Records—Steel and Wood Transmission Lines, Comparative. Booker....686–9; disc. 689
Performance Specification, Governors and the AIEE-ASME Governor. Schwendner, Astley....1330–2
Performance, The Eccentric Pole Face—A Means to Better D-C Machine. Baker....1107–10
Phenomena of 3-Conductor Cables, Transient Temperature. Wollaston....1284–95; disc. 1295
Philadelphia, 69-Kv Pipe-Type Cable Circuits in. Kidder, Van Antwerp....550–6; disc. 556
Photographic Purposes, An Electro-Optical Shutter for. Zarem, Marshall, Poole....84–91
Pile Voltage Regulators, Fundamentals, and Design Improvements, Aircraft Carbon-. Austin, Richards....983–7
Pipe, A-C Resistance of Segmental Cables in Steel. Meyerhoff, Eager....816–29; disc. 829
Pipe-Type Cable Circuits in Philadelphia, 69-Kv. Kidder, Van Antwerp....550–6; disc. 556
Pipes, The Temperature Rise of Buried Cables and. Neher....9–17; disc. 17
Plan for a Metropolitan Area, A 66-Kv Subtransmission. Smith, Michelson....908–12; disc. 912
Plant, A 3,000-Horsepower Gas Turbine Power. Haverstick....458–60
Plant Loading Schedules, Co-ordination of Fuel Cost and Transmission Loss by Use of the Network Analyzer to Determine. George, Page, Ward....1152–60; disc. 1160
Plant on Sudden Load Reduction, The Performance of a Topped Steam Power. Noest....1348–56
Plants Prefer Diesel-Electric Switching Locomotives, Industrial. Woods....697–700
Polar Vector Indicator. Walker, Waynick, Sulzer....154–9
Pole Face—A Means to Better D-C Machine Performance, The Eccentric. Baker....1107–10
Pole Lines, Rubber Insulators for. Wheeler, Markley....195–7
Pole Motor. The Field Fluxes of the Shaded-. Kimberly....273–7
Porcelain Potheads, A New Technique in Manufacture of Soldered. Papp, Nicholas..1258–60; disc. 1261
Potential Residential Electric Load, The Heat Pump—Its Significance as a. Bary....1–8
Potheads, A New Technique in Manufacture of Soldered Porcelain. Papp, Nicholas.1258–60; disc. 1261
Potheads 69,000 Volts and Below, Design Fundamentals of. Nicholas....1263–7; disc. 1267
Power Factor of Unbalanced Sinusoidal 3-Phase Circuits, The Vector. Lamb, Brandt....507–09
Power-Flow Studies, Equivalent Circuits for. Ward....373–80; disc. 380
(Power Generation) A New Automatic Load Control for Turbine Generators. Ruud, Farnham....1337–42; disc. 1342
Power Generation and Other Applications, Two Gas Turbines for. Howard....461–5; disc. 465
(Power Generation) Determining Incremental Regulation and Dead Band of Governors on Steam Turbine Generators Under System Load Conditions. Tornquist, Wade....1343–7
(Power Generation) Electrical Design Features—Steam-Electric Generating Station P of the Pacific Gas and Electric Company. Benson...1013–20; disc. 1020
Power Generation, Gas Turbines in Stationary. Hague....467–8
(Power Generation) Governors and the AIEE-ASME Governor Performance Specification. Schwendner, Astley....1330–2
(Power Generation) Outage Rates of Steam Turbines and Boilers and of Hydro Units. (Committee Report)....450–7
(Power Generation) Some Oscillographic Methods of Investigating Mechanical and Hydraulic Conditions During Operation of Hydroelectric Units. Engvall....993–6
(Power Generation) The Transient Behavior of the Two-Stage Rototrol Main Exciter Voltage Regulating System as Determined by Electrical Analogy. Carleton....59–63
Power-Level Recorder, A Square-Law. Clark, Turner, Williams....476–82
Power-Line Carrier Equipment, A Proposal for Broad-Band Coupling of. Miller....1028–30; disc. 1030
Power Line Carrier for Relaying and Joint Usage. Part I. Hampe, Storer....864–7; disc. 871
Power Lines, Line Tuning Equipment Used With Coaxial Cable for Carrier Current Installation on. Sutton....44–8; disc. 48
Power Plant, A 3,000-Horsepower Gas Turbine. Haverstick....458–60
Power Plant on Sudden Load Reduction, The Performance of a Topped Steam. Noest....1348–56
Power Rating of Radio-Frequency Cables, The. Mildner....289–98; disc. 298
Power Supplies for Coaxial Systems. Spencer..627–30
Power Supplies for Microwave Relay Systems. Ward....631–6
Power Swings, Graphical Method for Estimating the Performance of Distance Relays During Faults and. Warrington....608–20; disc. 620

Temperature Phenomena of 3-Conductor Cables, Transient. Wollaston....1284–95; disc. 1295
Temperature Rise from Early Heat Run Data, Production of Ultimate. Ryan....1164–6
Temperature Rise of Buried Cables and Pipes, The. Neher....9–17; disc. 17
Temperature Rise of Cables in a Duct Bank, The. Neher....540–6; disc. 546
Temperature Rise Values for D-C Machines. Part I. (Committee Report)....206–12; disc. 212
Temperature Rise Values for D-C Machines. Part II. (Committee Report)....1118–23; disc. 1123
Temperature, The Measurement of Dielectric Loss at High Frequencies and Under Changing. Whitehead, Rueggeberg....520–4
Terminals for Coaxial Systems, Television. Morrison....1193–9
Test Circuits for Protective Relays, Novel. Sonnemann....1249–54
Test Code for Electric Brushes, Progress Report in AIEE. (Committee Report)....1126–8
Test Procedures and Methods of Analysis of Results to Research Problems in Magnetic Recording, Application of Experimental. Thompson....407–17
Tests Evaluate Thermal Endurance of Class H Insulation and Silicone Varnish, Motor. Grant, Kauppi, Moses, Gibson....1133–8
Tests of Oil Circuit Recloser Substantiate Analytical Co-ordination Method, Field. Auer, Branflick, Woodward, McKinley....801–08; disc. 808
Theoretical and Practical Approach to the Design of High-Voltage Cable Joints, A. Short....1275–80; disc. 1280
Theory and Experimental Confirmation of the Moving Coil Fluxmeter, General. Higgins, Robertson....897–907; disc. 907
Theory of Inherent-Overheating Protection Under Running Overload Conditions, Fundamental. Veinott, Schaefer....266–70; disc. 270
Theory of Multiple Cage Induction Motors, General. Chang....1139–43
Thermal Converter for Telemetering and Totalizing, A. Downing....879–84; disc. 884
Thermal Demand Meters, Heat Flow Ratio as a Design Parameter in. Nelson....885–90; disc. 890
Thermal Endurance of Class H Insulation and Silicone Varnish, Motor Tests Evaluate. Grant, Kauppi, Moses, Gibson....1133–8
Thermal Movement of Moisture in Soil, The. Mickley....330–3; disc. 333
Thermal Volt-Ampere Demand Meter, A New. Douglass, Morong....79–83; disc. 83
Three-Phase Circuits, The Vector Power Factor of Unbalanced Sinusoidal. Lamb, Brandt....507–09
Thyrite in Power Transformers, Use of. Meador....959–64; disc. 964
Tie—A Steady-State Analysis, The Torques of the Synchronous. Finzi, McConnell....1147–52
Tie, The Geometric Loci of the Synchronous. Finzi, Wellard....168–71
Time Division Multiplexing System, A. Boothroyd, Creamer....92–7
Time in Testing Life of Incandescent Lamps, Saving. Purcell....730–2
Time of High-Voltage Fault-Arc Paths, Deionization. Harrington, Starr....997–1003; disc. 1003
Times as a Factor in Applying High-Speed Reclosing Circuit Breakers, Insulator Flashover Deionization. Boisseau, Wyman, Skeats....1058–66; disc. 1066
Topped Steam Power Plant on Sudden Load Reduction, The Performance of a. Noest....1348–56
Torque Curves, Dynamic Braking Control of D-C Series Motors—Experimental Study of Speed-. Heumann....560–4
Torques of the Synchronous Tie—A Steady-State Analysis, The. Finzi, McConnell....1147–52
Totalizing, A Thermal Converter for Telemetering and. Downing....879–84; disc. 884
Trackless Trolley Operation in Rhode Island. Blomquist....397–402
Traction Motors, Twenty-Five Years Progress in the Design of. Baldwin....132–7
Traffic Control for Railroads, Centralized. Hailes....1167–73
Transfer Function Loci for Servomechanism Components and Systems, Graphical Determination of. Thomas, Easton....307–14; disc. 314
Transformations Useful in Constructing Analogs of Linear Vibration Problems, Summary of. Corbett....661–4
Transformer and Secondary Conductor Economics, Distribution. Brady....483–6; difc. 486
Transformer Audio Noise Problems on an Electric Power System. Murray....740–7; disc. 747
Transformer Characteristics, Rectifier. (Committee Report)....1305–11
Transformer Manholes and Vaults: Design and Ventilation. Porter....534–9
(Transformer) Some Fundamentals of D-C Controlled Reactors with Resistive Load. Storm....188–94; disc. 194
Transformer Stations, Automatic Grounding and Air-Break Switches for Protection of. Ricker....851–6; disc. 856
Transformer System, Economic Loading of a. Levine, Smith....733–8; disc. 738
(Transformer) Universal Curves for D-C Controllable Reactors. Johnson, Merrell, Alley...31–7; disc. 37
Transformers, A Method for Designing Pulse. Kirschbaum, Warren....971–8
(Transformers) A Small High-Voltage Bushing Design for High Altitudes. Vogel, Hart....761–4
Transformers, Controlled Temperature and Insulation Protection in the Operation of Power. Satterlee, Reed....753–8; disc. 759
Transformers, Extremes in the Insulation Co-ordination of Oil Insulated. Vogel....965–8; disc. 968
Transformers, Lightweight Aircraft. Stephens..1073–8
(Transformers) Standardization of Reactor Ratings. Kierstead, Thomason....955–7; disc. 957
Transformers Under Short-Circuit Conditions, Heating of. Montsinger, Halsey....947–52; disc. 952
Transformers, Use of Thyrite in Power. Meador....959–64; disc. 964
Transformers with Bonneville Power Administration Transmission System, Matching Electrical Characteristics of McNary Generators and. Hoard, Weiner....1022–5; disc. 1026
Transient Behavior of the Two-Stage Rototrol Main Exciter Voltage Regulating System as Determined by Electrical Analogy, The. Carleton....59–63
Transient Characteristics of D-C Motors and Generators. McClinton, Brancato, Panoff....1100–06
Transient Fault Locator for High-Voltage Transmission Lines, A. Spaulding, Diemond....1005–10; disc. 1010
Transient Performance of Servomechanisms, Comparison of Steady-State and. Chestnut, Mayer....765–77
Transient Temperature Phenomena of 3-Conductor Cables. Wollaston....1284–95; disc. 1295
Transients in 2-Phase Synchronous Machines. Wilson....1360–7
Translations, Codes and. Myers....592–7
(Transmission) A 66-Kv Subtransmission Plan for a Metropolitan Area. Smith, Michelson....908–12; disc. 912
(Transmission) Connection Arrangements and Protective Practices for Shunt Capacitor Banks. Clark, Farnham....1226–30; disc. 1231
(Transmission) Deionization Time of High-Voltage Fault-Arc Paths. Harrington, Starr....997–1003; disc. 1003
(Transmission) Design and Experience With 4-Kv Primary Network Systems in the Washington Area. Lank....712–16; disc. 716
(Transmission) Hy-Therm Copper—An Improved Overhead-Line Conductor. Hickernell, Jones, Snyder....22–7; disc. 27
(Transmission) Improvements to Oklahoma City Primary Network. Brady....701–02; disc. 702
Transmission Line at Carrier Current Frequencies, Loss Measurements Made on Underground-Cable Overhead-Conductor 132-Kv. Cornelius, Storer....597–601
Transmission Line Clamps, Magnetic Heating of. Crabb, Sheadel....1032–5
Transmission Line Design and Performance Based on Direct Lightning Strokes. Harder, Clayton....439–46; disc. 447
Transmission Line Joints by Means of a Bolometer, Detection of Overheated. Leslie, Wait....64–8; disc. 68
Transmission Lines, A Transient Fault Locator for High-Voltage. Spaulding, Diemond....1005–10; disc. 1010
Transmission Lines Along Uniformly Rotating Reference Frames, Stationary Networks and. Kron...690–6
Transmission Lines as Affecting Ground-Fault Neutralizers, Report on Survey of Unbalanced Charging Currents on. (Committee Report)....1328; disc. 1329
Transmission Lines, Comparative Performance Records—Steel and Wood. Booker..686–9; disc. 689
Transmission Lines from the New Sunbury Generating Station, Relaying of. Green, Oewel, Ramsaur....873–7; disc. 877
Transmission Loss by Use of the Network Analyzer to Determine Plant Loading Schedules, Co-ordination of Fuel Cost and. George, Page, Ward....1152–60; disc. 1160
(Transmission) Primary Networks on the Duquesne Light Company System. Holben, Lange....704–09; disc. 709
(Transmission) Report of a Survey on the Performance of Shunt Capacitors. (Committee Report)....1200–06; disc. 1206
(Transmission) Report on the Operation and Maintenance of Shunt Capacitors. (Committee Report)....1208–18
Transmission Speed, Considerations on Facsimile. Burkhard....418–23; disc. 423
Transmission System, Matching Electrical Characteristics of McNary Generators and Transformers with Bonneville Power Administration. Hoard, Weiner....1022–5; disc. 1026
(Transmission) The Calculated Risk of Operating Capacitors Without Individual Fuses. Brooks....1219–25; disc. 1225
(Transportation, Air) Aircraft Carpon-Pile Voltage Regulators, Fundamentals, and Design Improvements. Austin, Richards....983–7
(Transportation, Air) An Electric Deicing System for Aircraft. Giloy....1051–7

Preface

The 1949 TRANSACTIONS (volume 68) of the American Institute of Electrical Engineers will be published in two parts.

Part I contains technical program papers and related discussions presented at general meetings and District meetings during the first half of the calendar year as follows:

1. Winter General Meeting, New York, N. Y., January 31–February 4, 1949.
2. South West District Meeting, Dallas, Tex., April 19–21, 1949.
3. Summer General Meeting, Swampscott, Mass., June 20–24, 1949.

Forty-two Summer General Meeting papers are included in Part I. The remainder of the Summer General Meeting papers will be included in Part II together with the approved papers and related discussions presented at the Pacific General Meeting and the Fall General Meeting.

Full correlation of all material in this volume has been accomplished by means of the multientry index beginning on page 791. Reference to any of the several subject entries for a technical paper will lead directly to the paper and to any published discussion on that paper.

Statements and opinions given in papers and discussions published in TRANSACTIONS are the expressions of contributors for which the American Institute of Electrical Engineers assumes no responsibility.

Part II of Volume 68 is expected to be available for distribution early in 1950.

The Heat Pump—Its Significance as a Potential Residential Electric Load

CONSTANTINE BARY
MEMBER AIEE

THE NAME heat pump as used herein describes a device which transfers heat from one temperature level to another by means of an electrically-driven compressor. When such a device takes heat from a source of relatively low temperature and makes it available at a higher one, it is said to operate on a "heating cycle," and conversely, when it removes heat from a space of relatively high temperature and discharges it elsewhere (at a still higher temperature) it is said to operate on a "cooling cycle." In either case, fundamentally it does not create heat energy as such; it only conveys the available heat of a particular source from one temperature level to another, and thus combines within itself the ability to either heat or cool a given space.

The fundamental thermodynamic principles of this device have been known for almost a century. Its operation on the cooling cycle has had extensive practical application in refrigeration, and in air conditioning of homes and other buildings. But, because of many technical difficulties and relatively high first cost, its operation on the heating cycle has had only limited application. For the most part it has been confined to commercial establishments largely in the southern part of the United States, or where reliable supplies of underground water are available. More recently, however, and due to certain technical developments, extensive interest has been shown throughout the electric utility industry, and by the public at large, in its possibilities for a practical method of heating homes electrically with the accompanying advantages of cleanliness, absence of combustion, ease of operation and general comfort and convenience.

The use of electricity in one form or another for heating homes has been considered off and on over a span of many years throughout the electric utility industry. It is generally conceded, however, that, at the existing state of the art, electricity cannot compete in cost for house heating, on a direct energy conversion basis, with other fuels such as coal, oil, or gas customarily used. This is true even under existing inflated prices in territories where a good grade of furnace coal for household use sells for about $15 per ton, fuel oil for about $0.10 per gallon and manufactured gas for about $0.70 per thousand cubic feet. There are three fundamental reasons for this handicap:

1. The present-day over-all efficiency involved in producing and distributing electricity from the heat contained in the fuel at the generating station to the heat contained in the electric energy delivered to the premises of residential customers is comparatively low, being in the order of 15 to 25 per cent, even though this is offset to a considerable extent by the fact that the effective utilization of the heat in fuels such as coal, oil, or gas by conventional house heating equipment is in the order of 50 to 75 per cent, as compared to 100 per cent utilization of the heat energy in electricity for heating purposes.

2. The magnitude of the investment required for the production, bulk power, transmission, transformation and distribution facilities with the related costs in carrying charges and operating expenses.

3. The relatively low diversified and undiversified annual load factors produced by the heating load of an average home result in comparatively high unit cost per kilowatt-hour.

Table I illustrates this point, using a home requiring 100,000,000 Btu during an average heating season at fuel prices now generally prevailing in a large metropolitan area of the Middle Atlantic states. The price of electricity is assumed at $.025 per kilowatt-hour to approximate the cost of supplying this service under the low annual load factor of the house heating load. The comparison is confined to costs applicable to fuel only. These numbers do not purport to represent a complete comparison of the total costs of heating with various fuels, since investment costs, maintenance costs, and cost equivalents of many intangibles have been omitted purposely to simplify the illustrations of the major features of such a comparison.

It will be noted from Table I that, at the stated prices, the seasonal cost applicable to fuel (exclusive of fixed charges, maintenance, and intangible costs) of heating a house by electric resistance-type heaters is about four times that with manufactured gas, and about six times that with oil or coal.

Since, for a given method of electricity production and distribution its cost per kilowatt-hour depends primarily upon the annual diversified load factor of the load served, and since the annual diversified load factor of the house heating load is largely fixed by prevailing climatic conditions of the territory, it becomes evident that if it were possible to reduce the quantity of electricity required to do the job of house heating, say, by four times, then the total seasonal cost of electricity for heating would become as low as that of gas, the nearest high-grade house heating service.

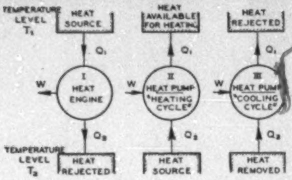
This is where the heat pump fits into the picture. It can be used to multiply the effectiveness of electricity for heating purposes, and thus make practicable the economical supply of energy for residential

---

Paper 49-1, recommended by the AIEE domestic and commercial applications committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted April 12, 1948; made available for printing November 4, 1948.

CONSTANTINE BARY is rate research engineer, Philadelphia Electric Company, Philadelphia, Pa.

The author acknowledges the valuable suggestions received from N. E. Funk, I. L. Craig, E. H. Bromer, A. H. Kidder, and G. E. Klapper of the Philadelphia Electric Company on the original manuscript of this paper, and the assistance of A. Abramovitz of that company in preparing the material contained therein.



$$Q = KT$$

$$\text{III COEFFICIENT OF PERFORMANCE} = COP_c = \frac{Q_2}{W} = \frac{Q_2}{Q_1 - Q_2} = \frac{T_2}{T_1 - T_2}$$

Figure 1. Principles of operation and performance of a heat engine and heat pump on a Carnot cycle

house heating by electric utilities, because, from thermodynamic considerations, a heat pump can be made to deliver from three to five kilowatt-hours in equivalent heat for every one kilowatt-hour required for its operation.

Scope

The object of this paper is to direct attention to the significant load characteristics that may be produced by the residential heat pump. This paper will touch briefly upon the general thermodynamic principles of heat pump operation; it will comment upon the nature of heat sources available for use with the heat pump and upon the applicability of several methods of heat distribution throughout the house; and it will demonstrate the major probable effects of the residential heat pump upon the load characteristics of the residential class of service. The actual values used herein represent experience with the load of one large electric utility system operating in metropolitan, suburban, and rural territories of the Middle Atlantic states.

A complete and precise picture of the significance of the residential heat pump cannot be made at this time, largely because this device is so new that its actual and possible engineering performance features are not firmly established, and because little if any experience is available as to its ultimate load characteristics. In this paper, however, recourse is made to the adaption of known characteristics of residential gas house heating loads, as determined by extensive tests made on a large system. It is assumed that these characteristics would be representative of the residential heat pump load as well.

No matter what ideas one may have at this time on the future heat pump situation, one is likely to be proved wrong by what actually may happen. But, notwithstanding the difficulty of foreseeing the future clearly and the futility of trying to determine precisely the world of tomorrow, it nevertheless seems highly desirable to obtain some idea now on the possible effects of the future residential heat pump load, so that the electrical industry can continue discharging its responsibility to broaden its usefulness just as in the past.

General Thermodynamic Principles of Heat Pump Operation

Figure 1 illustrates the well-known relationships of efficiency and coefficient of performance of an ideal Carnot heat engine, and that of a heat pump reflecting the ideal Carnot cycle of operation. In this figure, T_1 and T_2 are absolute temperatures, 460 + F (degrees Fahrenheit), with T_1 being higher than T_2; Q_1 and Q_2 the quantities of heat received from, or exhausted to some outside body, and W the work done by or on the system.

It will be noted from the formulas shown that since the difference between the temperatures T_1 and T_2 is always less than T_1, the coefficient of performance of a heat pump operating on a heating cycle will be always greater than unity. By algebraic transformation it may be shown too that for given temperature levels, the coefficient of performance for the heating cycle (COP_h) is equal to one plus the coefficient of performance for the cooling cycle (COP_c).

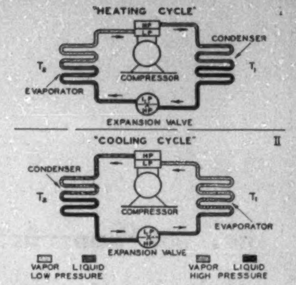

Figure 2. Schematic diagram of heat pump operation

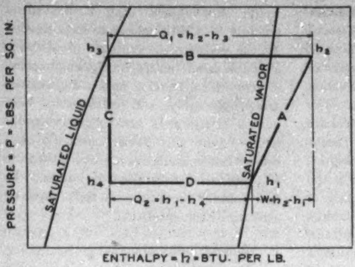
Figures 2 and 3 illustrate schematically and by means of a pressure–enthalpy diagram respectively, the fundamental thermodynamic principles of operation of a heat pump on an ideal vapor cycle, with its irreversible processes, employing as a working medium a fluid which can be made to absorb and surrender heat by an alternate process of vaporization and condensation.

When operating on a heating cycle (Figure 2-I) the low-pressure vapor, in the ideal case, coming from the evaporator at a low temperature, enters a compressor, where the vapor is compressed, with a resulting increase in its temperature and pressure. It is then passed to the condenser where it is made to give up its latent heat, and in doing so is condensed to a liquid which, flowing through an expansion valve, is reduced in pressure and temperature and is then returned to the evaporator, where it is turned to vapor by absorbing heat from an outside source which is at a higher temperature than the low-pressure liquid coming from the expansion valve.

More specifically from the pressure-enthalpy diagram of the ideal cycle (Figure 3) the vapor from the evaporator at point h_1 is compressed isentropically to h_2 through the application of work done on it from outside (so that the enthalpy at $h_2 = h_1 + W$). The compressed vapor is then condensed at a constant pressure to a liquid at point h_3, and in doing so it liberates the amount of heat $Q_1 = h_2 - h_3$. The liquid then is expanded at constant enthalpy through an expansion valve proceeding to the evaporator, where, in ab-

Table I. Comparison of Cost Applicable to Fuel for Heating a Home Which Requires 100,000,000 Btu During a Heating Season From September to May

Kind of Unit	Electric Resistance Heating (Kilowatt-hours)	Manufactured Gas (Thousand Cubic Feet)	Fuel Oil (Gallons)	Coal (Net Tons)
Btu per unit employed	3,415	520,000	140,000	24×10^6
Efficiency, per cent	100	75	65	50
Useful heat delivered to house per unit-Btu	3,415	390,000	91,000	12×10^6
Units required to heat house	29,283	256	1,099	8.33
Cost applicable to fuel:				
Price per unit	$0.025	$0.70	$0.10	$15
Cost of fuel	$732	$179	$110	$125
Cost of electricity for auxiliaries			$8	
Total	$732	$179	$118	$125
Approximate relation to cost of electric resistance heating	1	1/4	1/6	1/6



$$COP_h = \frac{Q_1}{W} = \frac{h_2-h_3}{h_2-h_1}$$

$$COP_c = \frac{Q_2}{W} = \frac{h_1-h_4}{h_2-h_1} = \frac{h_1-h_3}{h_2-h_1}$$

Figure 3. Pressure-enthalpy diagram of ideal vapor cycle for heat pump operation

A—isentropic compression
B—constant pressure condensation
C—constant enthalpy expansion
D—constant pressure evaporation

sorbing heat from the outside, it vaporizes and in doing so gains heat $Q_2 = h_1 - h_3$, completing the cycle by returning to the compressor.

When operating on a cooling cycle, the process is reversed, the evaporator becoming the condenser, and the condenser the evaporator. (Figure 2-II.)

The coefficients of performance of this ideal cycle are expressed by the following relationships:

When operating on a heating cycle

$$COP_h = \frac{Q_1}{W} = \frac{h_2-h_3}{h_2-h_1} \qquad (1)$$

and when operating on a cooling cycle

$$COP_c = \frac{Q_2}{W} = \frac{h_1-h_3}{h_2-h_1} \qquad (2)$$

Since $COP_h = 1 + COP_c$, the foregoing equations may be rewritten to:

$$COP_h = 1 + \frac{h_1-h_3}{h_2-h_1} \qquad (3)$$

The coefficient of performance of the actual cycle of a heat pump will be lower than that of the ideal by the high- and low-side frictional pressure drop losses occurring in the actual cycle, the electrical losses of the motor driving the compressor, and the mechanical losses of the compressor. However, some of this decrease in the actual coefficient of performance may be offset by employing liquid-subcooling and liquid-suction vapor heat exchange.

Expressing these effects in terms of factors for application in the coefficient of performance formula of the ideal cycle, the formula for the actual cycle with subcooling and liquid suction heat exchange becomes

$$COP_h = 1 + e f_l f_h z \frac{h_1-h_3}{h_2-h_1} \qquad (4)$$

Where

e = the isentropic efficiency of the compressor-motor combination
f_l = the low-side pressure drop correction factor
fh = the high-side pressure drop correction factor
z = liquid subcooling and vapor heat exchange correction factor

Under a proper design and within the practical range of heat pump operation, the factors f_l and f_h will be always lower than unity and the factor z will be generally higher than unity, with their product approximating unity. Therefore the isentropic efficiency of the compressor-motor combination is left as the major determining factor in establishing the coefficient of performance of an actual cycle as compared with an ideal one.[1]

In actual practice, in addition to the electric energy requirements of the compressor-motor, there may be energy required for auxiliaries such as fans and pumps which are functional parts of the heat pump. The energy used by them must be considered in establishing the over-all coefficient of performance of a heat pump assembly.

Figure 4 is presented from data recently developed by W. Parkerson[2] to illustrate the practical range of variation in the coefficient of performance of a heat pump (exclusive of auxiliaries) operating on a heating cycle for selected values of condenser and evaporator temperatures, and for performance cycles ranging from the ideal Carnot cycle through to the actual cycles utilizing Freon 12 (CCl_2F_2), and employing ideal, possibly attainable and present-day efficiencies of compressor-motor combinations. It will be noted that, the smaller the difference between the condenser and the evaporator temperatures, the higher is the coefficient of performance, indicating that for any given condenser temperature, one should strive for as high an evaporator temperature as possible in order to obtain the highest coefficient of performance of the heat pump; and similarly for any given evaporator temperature, one should strive for as low a condenser temperature as possible to obtain the highest coefficient of performance.

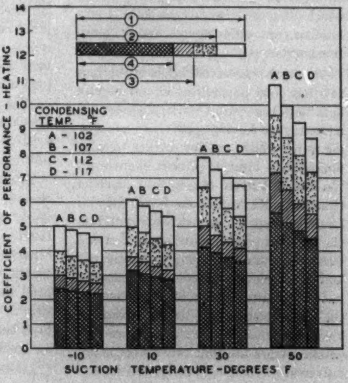
It is for this reason that temperature characteristics of heat sources become of major significance in the practical performance of heat pumps, and that temperature levels of heat distribution media become of great importance in the design of the heating system employing a heat pump.

Heat Sources and Heat Distribution

There are three principal heat sources available to a heat pump today: air, water, and earth. They may be used separately or in combination. Each has

Figure 4. Range in coefficient of performance of heat pump on a "heating cycle" for selected suction and condensing temperatures

1. Carnot cycle
2. Ideal cycle with Freon-12 (isentropic compression with 100 per cent compressor—motor efficiency, no super-heat, no sub-cooling)
3. Possibly attainable with Freon-12 (compressor efficiency 85 per cent, motor efficiency 85 per cent, 10 degrees super-heat, 10 degrees sub-cooling)
4. Present-day commercial-type compressor (5 horsepower)



its own physical and economic advantages and disadvantages.

The air possesses the advantage of being universally available, free of charge. However, possible wide fluctuations of its temperature and especially the level of its dew point temperatures, are limiting factors in its universal use as a practical heat source for heat pumps. Its temperature is lowest at times when house heating requirements are at a maximum, which is obviously the reverse of what is required to limit the size of installed capacity of the heat pump and to obtain the highest coefficient of performance. It is for this reason that the practical application of air as the sole source of heat for house heating at present is limited to climates where the temperature does not drop much below 35 to 40 degrees Fahrenheit. However, in climates where the temperature drops below those values, for part of the total heating season, it still may be an economical source of heat for the heat pump in combination with another heat source, which would be called upon, at intervals, to supply either the deficiency in, or even the total heat of, the requirements during that time. In a climate such as is experienced in the Middle Atlantic states, about 50 per cent of the heating requirements as measured by degree days for an average heating season, occur at times when the daily mean outdoor temperature is 35 degrees Fahrenheit and higher.

Water from a flowing stream, from wells, or from city water mains is a good source of heat. It possesses the advantage of a relatively high temperature which is not subject to very wide fluctuations, but its disadvantages are that it is not universally available free of charge, and its use, in comparatively large quantities is undesirable, and usually entails costs which often are so high as to make it prohibitive from an economic and competitive point of view.

The earth several feet below the surface also has good possibilities as a source of heat for a heat pump.[3,4] It possesses the advantage of having relatively high temperatures which are not subject to wide fluctuations. But, at present, there is not too much known of its heat transfer characteristics at various levels for different soil types, moisture content and for the different conditions of extraction and dissipation under varying temperatures; and the ultimate effects of unbalanced heat withdrawal from, and absorption by, the earth upon its long-term temperature levels are a matter of conjecture now. Its disadvantages are that this source is not universally available in the quantities and qualities required, and heat from it cannot be obtained free of charge, since work would be needed to embed into the earth, at the desired depth necessary, lengths of piping for the purpose of heat extraction or dissipation, as the case may be. The possibilities for its use as a heat source are so attractive, however, that in recent years they have aroused considerable interest in the subject of application of the heat pump principles for the heating of homes even in the northern and middle temperature zones of the United States, which contain by far the major portion of the country's population. As a matter of fact, it is the opinion of the author and many others, that at the existing state of development of the art, unless the earth proves to be an economical heat source, the application of the heat pump principle for heating homes through the middle and northern belts of the United States can be relegated to the realm of theoretical discussion rather than be considered as a large volume commercial reality for the immediate future.

While the heat source is of major significance in the practical application of the heat pump, the medium employed for conveying the heat throughout the house is equally significant. As pointed out in Figure 7, the higher the temperature of the condenser the lower the coefficient of performance. The temperature level in the condenser coils is limited by the existing availability of refrigerants and by the practical considerations of higher pressures (required by the higher temperatures) on the design of compressors, piping, joints, and valves. Thus, from the standpoint of the heating cycle alone, practical condenser temperatures cannot be expected to be much above 120 degrees Fahrenheit. This level of temperature rules out steam for a heating medium, circumscribes greatly the conventional application of hot water, and frequently requires a redesign of heat distribution facilities when using air for the heating medium; and from the standpoint of the cooling cycle, the air as a cooling medium appears at this time to be the only practical means for accomplishing the desired job.

In addition to the foregoing considerations of heat sources and methods of heat distribution in the home, present indications are that the "first cost" and maintenance cost of a heat pump would be higher than those of conventional fuel-fired heaters and about the same as the sum of the costs for a conventional fuel-fired heater and a central system summer air conditioner.[5]

Looking realistically at the problem, it would thus appear that a substantial amount of additional research is needed on the economical methods of utilizing available heat sources, on the engineering of economical heating media and on the design, assembly, and operation of heat pumps, refrigerants, and accessory equipment, before this device could be considered as a commercial reality, within the reach of a large number of homes. To find popular acceptance it must have at least nine basic qualities:

1. High reliability of operation.
2. High efficiency of performance.
3. Low maintenance cost.
4. Reasonable "first cost."
5. Compactness.
6. Neat appearance.
7. Easy accessibility of all parts for repair, maintenance, and replacement.
8. Minimum noise level and vibration.
9. Adaptability to wide application in new, as well as in existing, home heating systems.

Effects on Residential Load Characteristics

Although the use of the heat pump for the heating of homes at present is far from a commercial and large volume reality, it possesses so much appeal to the popular mind on its cleanliness, convenience, and a year-round job of automatic air comfort in the home, that it cannot be ignored by either the utilities or manufacturers of equipment as to its future possibilities and probable effects on the load characteristics of the utility supplying the electric service for its operation. The potential magnitude of this load is great as evidenced by the fact that, if only 10 per cent of the residential customers of the system referred to in this paper were to be equipped with this device, under the performance levels now thought possible, there would be obtained an addition to that system's peak of about one-sixth of its entire 1947 peak load from all classes of service: residential, commercial, industrial, municipal, traction, and sales to other electric utilities. This increase in system peak is about equal to the peak load of the entire residential class of customers represented by a community of some 3,000,000 people. Obviously, a potential load of this magnitude deserves careful study as to its economic implications, especially since, in addition to its size, all indications are that its annual load factor and group coincidence factor[6] will be much different from those experienced by the present size and volume load of the residential class of customers.

There is no precise way to determine the average size of the house heating heat pump load which may be served in the future by any given utility system, because of the many variables involved in such a determination. At the beginning, and for many years to come, until substantial levels of saturation of this device are obtained, the average size of heat pumps may vary from year to year, depending upon the kind of homes in which they will be installed, the relative penetration of the various segments of the residential market, and the types of heat pumps used.

If past experience in the acquisition of the gas space heating load is any indication of the probable trends in the acquisition of the residential electric heat pump load, one may expect, at the start, the average size of heat pumps to be comparatively high, gradually decreasing with an increase in the saturation of this device. To give some indication of this probable average unit size of the heat pump load for saturations, equivalent to those now expected to be obtained for gas space heating in this territory, the assumption will be made that the heating requirements of an average home using a heat pump will approach the average size of the gas space heating installations, which experience indicates will approximate 250,000 cubic feet of 520 Btu manufactured gas per installation for a heating season having a normal temperature deficiency of 4,750 degree days. Based on these data, and an assumed gas heater efficiency of, say 75 per cent, the calculated heat input to the house for a 70 degree Fahrenheit differential will be close to 55,000 Btu per hour. But the heater capacity of such an average home, on the basis of actual experience with gas heating installations in this territory, should be close to 100,000 Btu per hour. The difference between the calculated heating requirements, and the actual heater capacity of an average installation is due to many factors which, among other things, include the provision for the desired quickness of heat recovery from a given low temperature level in the house, the effects of high-wind velocities on days of low outdoor temperature, which are not reflected by the above calculations, and the practical necessity for selecting heaters of a size next higher to the capacity indicated by calculations, because of the availability in practice of heating units only in standardized sizes.

It is possible that heat pump installations need not provide for such a wide margin between capacity and calculated maximum requirements, and that users of heat pumps must be taught to use this device differently from a conventional fuel-fired heating installation. Also, the economics of heat pump installations may preclude the use of such wide margins. But to assure adequate home heating service with heat pumps, practical necessity will require the provision of some definite margins. What the actual magnitude of this margin may be for an average installation is at this time only a matter of opinion; but for purposes of this paper it will be assumed that an average home with heat requirements, as calculated previously, of 55,000 Btu per hour will use a heat pump installation of 85,000 Btu per hour capacity at an outdoor temperature of zero degrees Fahrenheit. Its electrical input will be close to 7 kw with a coefficient of performance of $3^{1}/_{2}$ which, although not as high as desirable, appears to be at this time realistically attainable for the climatic conditions experienced in this territory. Assuming the annual coefficient of performance to be $3^{1}/_{2}$ also, such a heat pump on its "heating cycle" of operation would require about 8,200 kilowatt-hours for a normal heating season. For its "cooling cycle" of operation during a normal summer season it would require an additional amount of some 800 kilowatt-hours, based on results of tests made by the author in Philadelphia area on central system air conditioning installations in homes. The total electric energy consumption of such an average heat pump installation in this territory should thus be close to 9,000 kilowatt-hours for a normal year-round job of heating and cooling. The net additional amount of electric energy requirements, however, will be somewhat lower, because of displacement of existing electric equipment used in the home in connection with fuel-fired furnaces and summer ventilation. However, these effects will be neglected for purposes of this discussion.

For illustrative purposes, the 30-minute maximum demand of an average heat pump in this territory will be assumed at 7 kw. The corresponding diversified maximum 30-minute demand of this load on an average day of the coldest week in a year, approximating a daily mean temperature of 22 degrees Fahrenheit and an outdoor temperature at 7:00 a.m. of about 17 degrees Fahrenheit, will be around 4.9 kw per average installation, based on results of actual tests conducted by the author on residential gas space heating loads. Thus the annual diversified load factor of the heat pump load for its heating cycle of operation is assumed here to be substantially the same as that of the gas house heating load. In actual practice, however, it may be either higher or lower depending on the design of the unit, its relative efficiency of performance on cold days in comparison with the over-all record for the entire heating season, and whether a constant temperature is set on the house thermostat throughout the entire day, or if there is a higher setting during the daytime and at a lower one at night.

These factors, and others, will have a definite bearing upon the electric energy use during a heating season and upon the diversified maximum demands of the heat pump, which, in turn will influence the magnitude of its annual load factor.

Figure 5 shows illustrative winter period daily load curves of three types of average residential customers:

Curve A. A present-day type of ordinary-use customer having electric lighting, refrigeration, and small miscellaneous appliances.

Curve B. A present-day type of heavy-use customer having, in addition to the ordinary use, an electric range and a water heater.*

Curve C. An all-electric type customer, having, in addition to the heavy-use, a heat pump.

It will be noted from Figure 5 that on the average day of the coldest week of the winter period, the maximum diversified demand of the all-electric customer is estimated to be about 17 times that of the ordinary-use customer; and about three times that of the heavy-use type. Since the present saturation of electric ranges and water heaters in the Philadelphia area is relatively low, perhaps in the vicinity of 10 per cent for electric ranges and 5 per cent for electric water heaters, the size load of the all-electric customer of some 17 times that of the ordinary-use customer is more indicative of the magnitude of the problem faced by the utilities in meeting the requirements of this potential load by providing the necessary facilities in distribution lines, transformers, substations, transmission and generation than a comparison of it with the heavy-use customer. From Figure 5 it will be noted, too, that the peak load of the all-electric customer will occur in the morning, around 8 a.m., and that the load between 5 and 6 p.m. (the period of the present-day peak load of the residential class) will be about 65 per cent of the morning peak load, thus indicating that the heat pump load possesses diversity with respect to the present-day peak load of the residential class.

Figures 6 and 7 show respectively an

C—All-electric (heavy-use plus heat pump)

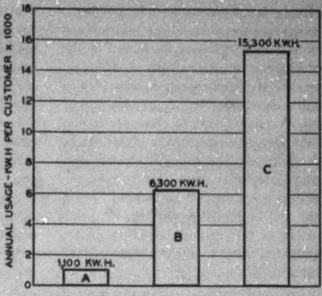

Figure 6 (right). Annual energy usage of three types of residential customers

illustrative comparison of the relative annual energy requirements of the three types of average residential customers, and the relative monthly distribution of this energy throughout the year. The annual energy requirements of the all-electric customer (bar C) are estimated to be about 15 times that of the ordinary-use customer (bar A), and about two and one-half times that of the heavy-use type (bar B). The monthly distribution of energy indicates that, while the winter months requirements for December, January and February of the all-electric customer (curve C) will be over 20 times the requirements of the ordinary-use customer (curve A), and from three to four times the requirements of the heavy-use type (curve B), the summer months' energy requirements of such a customer will be only ten times higher than those of the ordinary-use type, and only one-half higher than those of the heavy-use customer.

The principal data applying to the three types of average residential customers are summarized in Table II.

From the foregoing, it becomes evident that the annual load factor of an average all-electric customer with a heat pump will be lower than that of either the ordinary-use or the heavy-use residential customers, and that the coincidence factor of such a customer will be higher than that of both of these types. However, these comparisons alone are not fully indicative of the significance of the heat pump load because they fail to reflect the effects of the diversity which would exist between the peak load of an average all-electric customer having a heat pump and the peak load of the present-day residential class.

To illustrate this latter effect, Figure 8 is presented. It shows the progressive change in the annual load factors of the entire residential class load with an increase in the saturation of all-electric customers having heat pumps (curve X) and with an increase in the saturation of heat pumps for a given saturation of electric ranges and water heaters (curves Y and Z).

Among the many factors which enter into the appraisal of the economic significance of a given load supplied by an electric utility, the annual load factor is of major importance. It is a well-known fact that, with all other things equal, cost per kilowatt-hour of supplying electric service varies inversely with load factor in accordance with the laws of a hyperbola. The higher the load factor, the lower the unit cost per kilowatt-hour and conversely, the lower the load factor, the higher such unit cost becomes.

Curve X in Figure 8 shows the results for a residential class that starts out by having no electric ranges and water heaters, thus depicting the volume of the ordinary-use of the residential class load, which approaches the conditions now existing on the system referred to in this paper, and curves Y and Z show the results for a residential class that starts out by reflecting the present-day volume of the ordinary-use and stated electric range and water heater saturations. Curve Y illustrates the relationship for a 50 per cent electric range and 25 per cent electric water heater saturation, which may be considered to be within the practical range of accomplishment at some time in the future; and curve Z—for a 100 per cent saturation of these major appliances which can only be considered of theoretical significance depicting the possible (but not necessarily probable) upper limit in the saturation of these appliances. All three curves cover the range up to a 20 per cent heat pump saturation, which, from practical considerations, may not be reached for decades to come.

Curve X indicates that the addition of all-electric customers to an existing residential load of ordinary-use, at first improves the annual load factor of the residential class of this type. This improvement reaches a maximum at about an 8 per cent heat pump saturation and thereafter begins to recede reaching the same class load factor value at a heat pump saturation of 17 per cent as actually exists at 0 per cent. Beyond this point, however, a continued addition of this type of load results in a progressively diminish-

Table II. Electric Load Characteristics of Three Types of Average Residential Customers

	Type of Average Residential Customers Ordinary-Use A	 Heavy-Use B	 All-Electric C
Annual energy usage, kilowatt-hours	1,100	6,300	15,300
Annual diversified 30-minute integrated demand, kilowatts			
Winter average weekday maximum	0.35	2.0	6.0
Absolute maximum	0.41	2.1	7.0
Annual noncoincident 30-minute integrated maximum demand, kilowatts	1.0	5.0	12.0
Annual diversified load factor, per cent			
Based on winter average weekday maximum demand	35.9	36.0	29.1
Based on absolute maximum demand	30.6	34.2	25.0
Coincidence factor, per cent			
Based on winter average weekday maximum demand	35.0	40.0	50.0
Based on absolute maximum demand	41.0	42.0	58.3

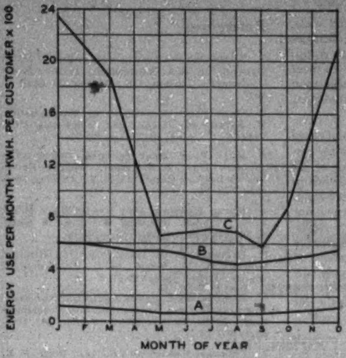

Figure 7. Monthly distribution of annual energy usage of three types of residential customers

A—Ordinary-use (lighting, miscellaneous appliances and refrigeration)

B—Heavy-use (ordinary-use plus electric range and water heater)

C—All-electric (heavy-use plus heat pump)

ing load factor of the class, approaching, at very high saturations, the value shown in Table II for the all-electric customer.

Curve Y indicates that the addition of heat pumps to a present-day residential load composed of ordinary-use and a 50 per cent electric range and a 25 per cent electric water heater saturation, improves the annual load factor of the residential class of this type within a rather small range of heat pump saturation. This improvement reaches a maximum at a heat pump saturation of about 2 per cent and thereafter begins to recede, reaching the same class load factor value at a heat pump saturation of around 4 per cent as actually exists at 0 per cent. Beyond this point a continued addition of heat pumps results in a progressively diminishing load factor of the class, but beyond an 8 per cent heat pump saturation, the annual load factor of this type of residential class is not much different from that of the residential class reflected by curve X for comparable heat pump saturations.

Curve Z indicates that the addition of heat pumps to a present-day residential load composed entirely of heavy-use customers (thus reflecting a 100 per cent electric range and water heater saturation) improves the annual load factor of the residential class of this type over a somewhat wider range of heat pump saturation. As indicated in the note on Figure 8, this improvement reaches a maximum at a heat pump saturation of about 25 per cent and, thereafter, begins to recede in a manner similar to that shown by curve X, and finally approaches at very high saturations the value shown in Table II for the all-electric customer.

The facts thus depicted in Figure 8 lead to the unavoidable conclusion that for electric utilities in the United States, geographically located in the latitude of the system referred to in this paper, the heat pump load does not offer possibilities of substantial improvement in the annual load factor of the residential class of service, within the probable saturation levels of this device which may be expected to be attained for some years to come. This fact, in turn, indicates that, with all other things equal, it would be impractical to justify a lower average rate per kilowatt-hour to the heat pump load than is obtained now from the addition of uncontrolled electric loads of other major usages in the home. As a matter of fact, under certain conditions, to cover all costs for the load factors of the residential class obtained with the heat pump, the average rate per kilowatt-hour applicable to this device may have to be even higher than is now available generally for uncontrolled usage of electric service in the home at the prices of the end blocks of residential rates. These prices now average over $0.017 per kilowatt-hour in the 16 largest cities of the United States, in the northern and middle temperature zones.

The inherent lack in ability of the heat pump by itself to improve the residential class annual load factor, at least insofar as these zones of the country are concerned, and its relatively large requirements for the supply of electric service, emphasizes the necessity for a proper engineering and design of the various component parts of the device to obtain maximum efficiency of performance, reliability of operation, and applicability in new and existing homes; and to minimize its first cost and all undesirable electrical features such as high-starting current, low-power factor, and high demand, which, otherwise, would have adverse economic effects upon the electric supply system and thus result in economic handicaps in the utilization of the electric service by this device.

It should be noted, however, that, for utilities located in territories similar to that referred to in this paper, the acquisition of the year-round heat pump load, with its inherently lower summer than winter electrical requirements, carries with it the ability to improve the economic significance of the residential summer air conditioning load which by itself in large quantities is not desirable, because of its low annual load factor. A proper implementation of the year-round heat pump load with additional summer air conditioning load for customers with

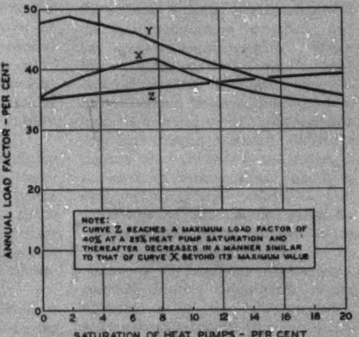

Figure 8. Relationships of trends in residential class annual load factors with increasing saturation of heat pumps

(Based on maximum diversified demands of average weekday for the coldest week of winter period)

X—Addition of all-electric customers with heat pumps to a residential class consisting of ordinary-use customers

Y—Addition of heat pumps to a residential class consisting of ordinary-use customers with a 50 per cent electric range and 25 per cent electric water heater saturation

Z—Addition of heat pumps to a residential class consisting of heavy-use customers (reflecting a 100 per cent electric range and electric water heater saturation) conventional heating systems, will tend to improve the over-all economic significance of the combined residential heating and cooling loads.

Conclusions

From the foregoing discussion it is possible to make the following observations:

1. The heat pump possesses the thermodynamic ability of removing the inherent economic handicaps present in electric resistance-type house heating. But to make it a commercial reality and within the reach of a large number of homes, it requires a substantial amount of additional research on the economical methods of utilizing available heat sources and on the engineering, design, and operation of compressor-motor assemblies, refrigerants, accessory equipment, and methods of heat distribution.

2. The electric load of an all-electric residential customer with a heat pump will be very large in comparison with the load of present-day average residential customers. The potential magnitude of this load and the difference in its load characteristics, from those of the present-day residential class, deserve careful study by electric utilities and manufacturers of power system equipment, to understand and be ready to meet the economic implications of this load upon the distribution, substation, transmission, and production systems.

3. By and large, within the practical range of probable heat pump saturations for residential house heating in the order of 20 per cent, the electric load of this device in the northern and middle temperature zones of this country will neither improve nor affect adversely (to any large extent) the annual load factor of the residential class of service. But for very large saturations of the device, substantial reductions in the annual load factor of this class of service can be expected, because of the inherently low annual load factor of the heat pump load.

4. To attain the optimum in the over-all competitive ability of the heat pump in regard to other methods of house heating, all efforts must be directed toward obtaining for this device the highest efficiency of performance, the highest reliability of operation, the lowest first cost, and the minimum of undesirable electrical features such as those of high-starting currents, low power factors, and high demands.

The Temperature Rise of Buried Cables and Pipes

J. H. NEHER
MEMBER AIEE

IN THE calculation of the temperatures attained by underground cable systems, the first practical calculation of that portion of the temperature rise occurring in the earth was presented by Doctor A. E. Kennelly in 1893.[1] The formula which he developed expresses this temperature rise as a function of the heat loss of the cable system, its geometry, and the thermal resistivity of the earth.

As factual data bearing on this aspect of the problem have been accumulated over the intervening years, a disagreement has been observed between values of earth thermal resistivity measured in the laboratory and the values of thermal resistivity required by the Kennelly formula in order to account for the temperature rises actually observed under field conditions. Modifications of the formula have been proposed as a result, and alternate procedures have been adopted. At the present time, the situation in this respect is confused and badly in need of clarification.

Apparently the objections to the use of Kennelly's method are caused by misunderstanding the relationships involved. As a starting point in obtaining a generally acceptable method of calculating the temperature rise in the earth, therefore, it seems desirable to review the conditions under which the Kennelly formula applies. It then will be practical to consider the effects of deviations from these conditions. As this investigation progresses, it will explain why values observed heretofore in the field and in the laboratory are in apparent disagreement, and also will clear up certain misconceptions as to the direction of heat flow from the cable system.

The Problem and Its Solution

The basic problem with which we have to deal consists of the determination of the temperature which will be attained by a cable system dissipating heat to the surrounding earth, which may have varying initial temperatures at different points due to the influence of other heat fields which are present. The potential complications of such a situation are obvious. In order to effect a practical solution, it is necessary to idealize it by simplifying the conditions considerably. The solution so obtained then must be checked by tests to establish the validity of the assumed simplifications.

The geometry is idealized by assuming the radiator to be cylindrical in shape. This is obviously valid for a cable buried directly in the earth, or for a pipe. In the case of a rectangular duct system, however, it requires the conversion of the basic dimensions to the radii of equivalent cylindrical surfaces.

Since we must deal with superimposed heat fields, it is necessary to consider the thermal resistivity of the medium as being unaffected by the temperatures which may be attained at various points in the general field. We further will idealize the conditions by assuming the thermal resistivity to be a constant throughout the field. Under this condition the superposition theorem becomes applicable; that is, the temperature change existing at any point in the general heat field becomes equal to the sum of the temperature changes produced at that point by each of the respective heat fields operating as if by itself. Thus, the temperature rise of any point in the field of a thermal radiator buried in the earth (including points on the surface of the radiator), above the initial or ambient temperature of that point, may be determined by considering only the temperature rise which would accompany the heat flow from the radiator into a medium assumed to have been initially at uniform ambient temperature throughout.

It is most important to recognize the fact that the resultant heat flow considered in this portion of the solution cannot represent the actual heat flow in the general field, which is a combination of effects caused by this and other heat sources. This feature will be discussed later in considerable detail.

For the purposes of obtaining a solution, therefore, the problem may be reduced to the determination of the temperature rise of a cylindrical radiator in the earth, as if the earth were initially at the same temperature throughout and has constant thermal resistivity. If the thermal radiator were located at the center of the earth, the ultimate temperature rise would be great, since the heat from the radiator would flow through a very large thermal resistance. With the radiator relatively close to the surface of the earth, as in the practical case, however, a relatively large portion of the heat will flow to the surface of the earth in the vicinity of the radiator, provided that it can escape to the atmosphere. The remainder of the heat flows into the earth, gradually heating it up until, in the ultimate, all of the heat eventually reaches the atmosphere.

The coefficient of heat transfer at the surface of the earth also is a factor. The conventional treatment is to assume that heat can pass freely to the atmosphere; because of the motion of air over the surface of the earth, there is no appreciable

Y., January 31–February 4, 1949. Manuscript submitted November 8, 1948; made available for printing November 12, 1948.

J. H. Neher is senior engineer with the Philadelphia Electric Company, Philadelphia, Pa.

The author wishes to acknowledge the very helpful contributions made by W. O. Smith, United States Geological Survey; F. H. Buller, General Electric Company; W. T. Brown, F. H. Housel and A. S. Mickley, all of the Philadelphia Electric Company; and to L. R. Ingersoll of the University of Wisconsin.

rise of temperature in this transfer. Conventionally, therefore, the surface of the earth is treated as if it were an isothermal plane. The refinement of accounting for the effect of the surface resistivity of the earth can be made later, without much difficulty.

We also must consider the time during which the heat flow from the cable system has been in effect, thus distinguishing between ultimate or steady-state, and transient conditions. In cable calculations it is customary to consider the steady-state rise, and we will solve the problem on this basis, indicating later the effect of time durations less than the theoretically infinite time implied.

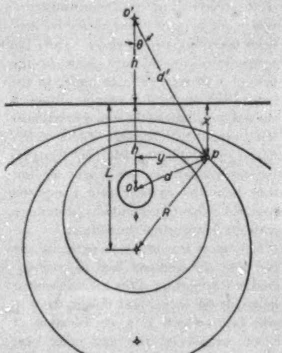

Figure 1. The development, in cross-section, of the isothermal surfaces surrounding a cylindrical thermal radiator in a uniform medium bounded by a parallel isothermal plane

The problem as now set up then is solved conveniently, as indicated in Figure 1, by the method of images given in detail in Appendix I. The resultant equation for temperature rise at any point P, in terms of the distances to the thermal center of the radiator d and to its image d', the heat flow Q_c, and the thermal resistivity ρ is

$$\Delta T_p = Q_c \frac{\rho}{2\pi} \log_e \frac{d'}{d} \text{ degrees centigrade} \quad (1)$$

It readily may be shown that the locus of all points having the same value of ΔT is a cylinder which is not concentric with the thermal center of the radiator, although, for relatively small diameters with respect to the buried depth, the eccentricity is negligible. Equation 1 may be rewritten in terms of the radius of any isothermal cylinder R, and the depth of its center L below the surface of the earth as

$$\Delta T_1 = Q_c \frac{\pi}{2\pi} \log_e \frac{L+\sqrt{L^2-R^2}}{R}$$

degrees centigrade (2)

This equation applies not only to the isothermals in the field of the radiator but to the surface of the radiator itself, if the radiator is, or may be considered to be, cylindrical in form. In this application, it has come to be known as the long form of the Kennelly formula.[1] For values of R small in comparison with D, both equations 1 and 2 reduce to the familiar form commonly known as the short form of the Kennelly formula

$$\Delta T_s = Q_c \frac{\rho}{2\pi} \log_e \frac{2L}{r} \text{ degrees centigrade} \quad (3)$$

If the thermal radiator is spherical in shape, the comparable form of equation 1 is

$$\Delta T_p = Q_c \frac{\rho}{4\pi} \left(\frac{1}{d} - \frac{1}{d'} \right) \text{ degrees centigrade} \quad (4)$$

and the resulting isothermals are distorted ellipsoids of revolution. (See Appendix I.)

Strictly speaking, the surface of the earth above a thermal radiator is not maintained as an isothermal plane, as is well evidenced by the fact that snow will melt directly above a buried steam main. This modification has been approached by Poritsky,[2] by assuming a constant and uniform surface resistivity β at the earth's surface. The resultant solution, as given in Appendix II, may be expressed as an additional term to be included in equation 1.

For practical purposes this additional term may be simplified to the form given below

$$\Delta T_p = \frac{Q_c}{2\pi} \left(\rho \log_e \frac{d'}{d} + 1.90 \frac{\beta \cos \theta}{d'} \right)$$

degrees centigrade (1a)

in which β is expressed in degree centigrade square centimeters per watt, d' in centimeters, and θ is the angle which d' makes with the vertical (See Figure 1).

In general, the effect of the additional term upon the temperature rise at the surface of the radiator is relatively small, and it usually may be neglected. Considering ρ to equal 60 degree centigrade centimeter per watt and β to equal 2,000 degree centigrade square centimeters per watt, which is felt to be conservatively high, and an 8-inch diameter radiator buried to a depth of 40 inches, its effect constitutes 9 per cent of the temperature rise at the surface of the radiator.

The effect at other points in the field may be more pronounced. At the surface of the earth directly above the radiator in the above case, the temperature rise is 16 per cent of the temperature rise at the radiator. At a distance 40 inches away on the surface of the earth, the temperature rise is 9.5 per cent of that at the surface of the radiator.

When equation 1a is used, the resulting isothermal surfaces, of course, will not be cylindrical.

Heat Flow from the Radiator

As indicated previously, the actual course of heat flow from the radiator is dependent upon all of the heat fields present. One of the objections most frequently raised to the use of the Kennelly formula arises from the mistaken notion that the formula infers that all of the heat from the radiator is always flowing to the surface of the earth.

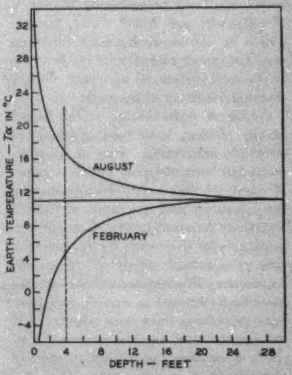

Figure 2. Typical vertical temperature gradients in the earth at extreme seasons of the year

To illustrate this point, let us consider the normal seasonal heat field present in the earth. This heat field results from a combination of the heat always flowing outward from the central core of the earth as it cools, and the heat received by solar radiation. In the summertime, heat is received from the sun, and as a result, the temperatures of the earth decrease with depth. In the wintertime the earth gives up heat to the atmosphere, and the temperature gradient is reversed. It will be found, by observation, that the average temperature over the year at any depth is quite constant, and that the difference between maximum and minimum temperatures decreases with the depth. Figure 2 shows the results of measurements made over a season in Philadelphia. Almost never is the earth at the same temperature at all depths, although this condition is approached roughly at midseasons.

Let us now assume that we have a cylindrical radiator buried in the earth to a depth equal to 10 times its radius, and that Q_c and ρ in equation 3 are such as to give a temperature-rise of 40 degrees centigrade at the radiator. By the relationships indicated in Appendix I, a family of eccentric circles, each representing a given value of temperature rise, may be determined and plotted on rectangular co-ordinates.

If at midseasons the earth were at a uniform temperature of 11 degree centigrade, each of these circles would represent an isothermal, the temperature of which is equal to the value of its temperature rise plus the 11 degrees centigrade. The resulting isothermals are indicated in Figure 3.

The lines of heat flow must pass from a higher isothermal to a lower isothermal in such a manner that they are always normal to the isothermals. Since, in this case, the isothermals are circles, the lines of heat flow are also circles, as shown in the dotted section of Figure 3, and all heat flow is ultimately toward the surface.

If we consider the earth's situation in February, the normal gradients are horizontal planes (lines in section), as indicated by Figure 2, and as shown at the extreme right-hand edge of Figure 4. By superimposing these horizontal ambient temperature lines upon our plot of temperature rises, we can determine, by addition, the resultant temperatures at the points of coincidence. The isothermals then can be drawn by the same procedure as is used in drawing topographical contour maps. Practically, it is more advantageous to solve directly for the rectangular co-ordinates of any point on a chosen isothermal. For a particular isothermal T_t and at a given depth (x co-ordinate) at which the ambient temperature is T_a, the value of temperature rise $\Delta T = T_t - T_a$. The horizontal position (y co-ordinate) of the point then is interpolated from the plot of temperature rises for the given depth.

Figure 4 shows the resulting isothermals determined by this procedure for February. The distortion of the isothermals from true circles is apparent, but it will be noted that the flow of heat is still upwards towards the surface.

Finally, if we go through the same process for the normal gradients existing in August, we obtain the interesting configuration shown in Figure 5. Here it will be noted that none of the heat liberated by the radiator goes directly toward the surface of the earth during this season, since the heat always flows in the direction from the higher toward lower isothermals.

It should be realized that Figures 3 to 5 are of academic interest only, and in no way contribute to the solution of the problem at hand. They have been included merely to indicate how the isothermals, which are actually present during stated conditions and which control the direction of heat flow from the radiator, may be synthesized by application of the principle of superposition.

Effect of the Time Factor on the Kennelly Formula

The Kennelly formula represents ultimate or steady-state conditions, which will be achieved strictly only after an infinite time, since the earth has thermal capacitance as well as thermal resistivity. In practical cable calculations, it is customary to reduce the cyclic heat flow from the duct system to an equivalent constant flow based on the average daily power loss. This equivalent constant heat flow is assumed to continue indefinitely, and we therefore are interested in the ultimate temperature rise as given by the Kennelly formula. In any attempt to back-calculate the thermal resistivity of the earth, however, by the application of the Kennelly formula to field tests which of necessity cannot be continued indefinitely, it is necessary to consider the attainment factor which represents the per cent of ultimate ΔT which will have been attained in the elapsed time t.

The attainment factors at the surfaces of cylindrical and spherical radiators are developed in Appendix III, and are plotted in Figure 7 against the dimensionless quantity $t\ \alpha/r^2$, in which α is the thermal diffusivity of the earth which is in turn equal to the reciprocal of the product of the thermal resistivity and the thermal capacitance.

Typical values for α, measured in Philadelphia, range from 23 to 42 square centimeters per hour. Thus, for an 8-inch diameter radiator buried 40 inches, it will be seen that, after 400 hours with $\alpha = 25$, the attainment factor is 0.85. In this connection it is well to note that a plot of ΔT versus t on rectangular co-ordinates is quite misleading, for if the curve is plotted to only 400 hours, it will appear that the ultimate substantially has been reached, whereas actually 15 per cent remains to be attained.

It should be noted that during the transient period, the loci of points having the same temperature rise are not circles, although the inner curves approximate this condition. By means of the formulas

Figure 3. Typical isothermals and lines of heat flow at midseasons

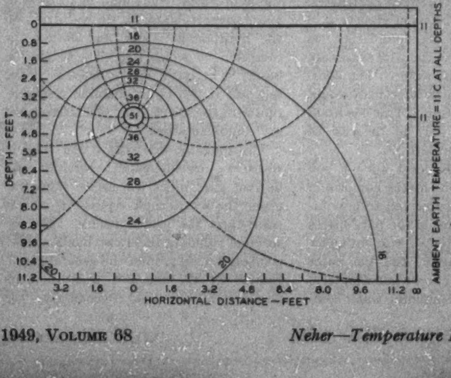

Figure 4. Typical isothermals and lines of heat flow at winter extreme

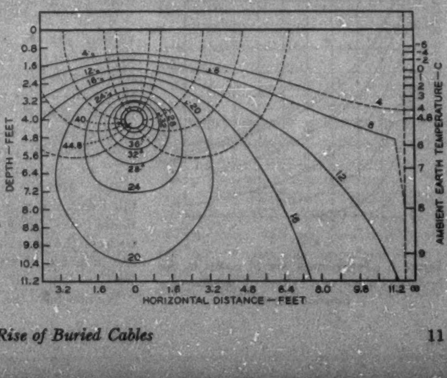

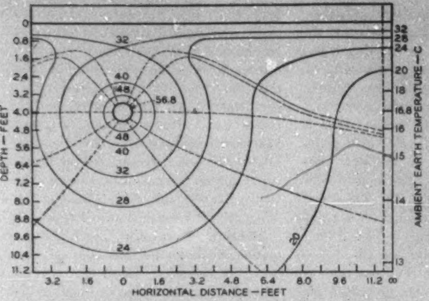

Figure 5. Typical isothermals and lines of heat flow at summer extreme

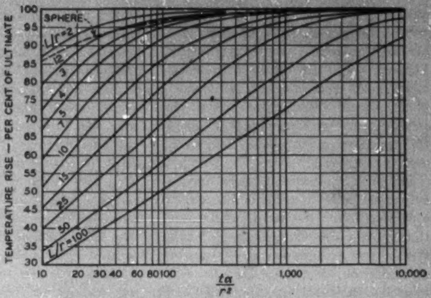

Figure 7. Attainment factors for cylindrical and spherical radiators

given in Appendix III, these loci may be plotted, and the isothermals, at any time after the inception of heat flow from the radiator and for any seasonal heat field condition, may be determined in the manner previously described if so desired.

Figure 6 shows the relative temperature rises of points in the horizontal plane through the center of a cylindrical radiator buried to a depth 10 times its radius, in terms of the ultimate temperature rise at the surface and for various values of $t\alpha/r^2$. From this it will be seen that, during the transient period at a given time, the relative temperature rise of a given point in terms of the corresponding rise at the surface of the radiator is less than that which will obtain after infinite time. In other words, the horizontal temperature gradient will be steeper than indicated by equation 1. This fact often has been observed during tests and has been interpreted incorrectly as a disagreement with the Kennelly formula. Actually, it is merely an indication that, at the time of the test observations, the heat field of the radiator was still in the transient period during which the Kennelly equation does not apply.

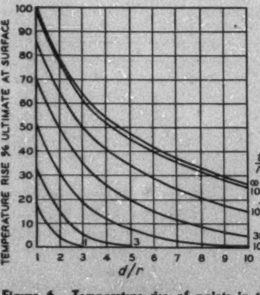

Figure 6. Temperature rise of points in the horizontal plane of a cylindrical radiator as a function of time

Thermal Resistivity of Soil and Moisture Migration

Thermal resistivity as a property of various soils in which the cable system may be located is a part of the science of soil mechanics, a subject with which cable engineers in general are not very familiar. While it is manifestly impossible to cover this extensive field in this paper, it does seem desirable to state briefly certain general principles and terminology which have important bearings on the problem at hand.

The thermal resistivity or conductivity of a given soil depends essentially on the type of soil, its structural arrangement, and its moisture content. Soil consists of discrete particles of irregular shapes and various sizes.[8] In the natural state, colloids are present which coat the sand and silt particles and collect them into aggregates. The pore spaces between the particles within the aggregates are quite different in size and must be distinguished from the pore spaces between aggregates.

Water is held in this soil structure in various degrees of freedom. Let us suppose first that all of the pore spaces are filled completely with water. The addition of any further water effectively would put the soil in suspension. This condition is of interest to us only in the case of cables located in river bottoms.

If we now suppose that such a soil sample, with the pore spaces completely filled with water, is subjected to gravitational forces, the water in the pore spaces between the aggregates will run out under the influence of gravity, and the water thus lost is termed "gravitational water."

We now have the remaining water completely filling the pore spaces within the aggregates, where it is held by capillary attraction. The amount of water present, expressed as a percentage of the dry weight of the soil sample is termed the "moisture equivalent" or "field capacity."

Proceeding further, let us assume that gravitational force is effectively increased (by a centrifuge) on our soil sample, so that the moisture is driven out of the capillary spaces within the aggregates, the water thus lost being termed "capillary water." This process will not continue until all of the water is withdrawn because some of the water is held very strongly as a thin film on the soil grains and on the colloid particles. The water thus held is the "hydroscopic water," and its amount on the basis of the dry weight is termed the "hydroscopic equivalent."

A point in the moisture scale slightly above the hydroscopic equivalent, termed the "wilt point," is of particular interest to agriculturists because plants are incapable of extracting moisture from the soil if the moisture present is less than this value.

If we now place our sample reduced to the hydroscopic equivalent in an oven at 105 degrees centigrade, we will drive off the hydroscopic water and obtain the condition on which the "dry weight" is based. There still will be moisture in the soil, but it will be in chemical combination with the soil elements; it is identified as "combined water."

The moisture content of the soils in which we are interested, therefore, will be that part which lies in the range between the hydroscopic equivalent or wilt point, and the field capacity. The respective values of these two limits are dependent not only upon the general classification of the soil but also upon its porosity in the field. Similarly, the

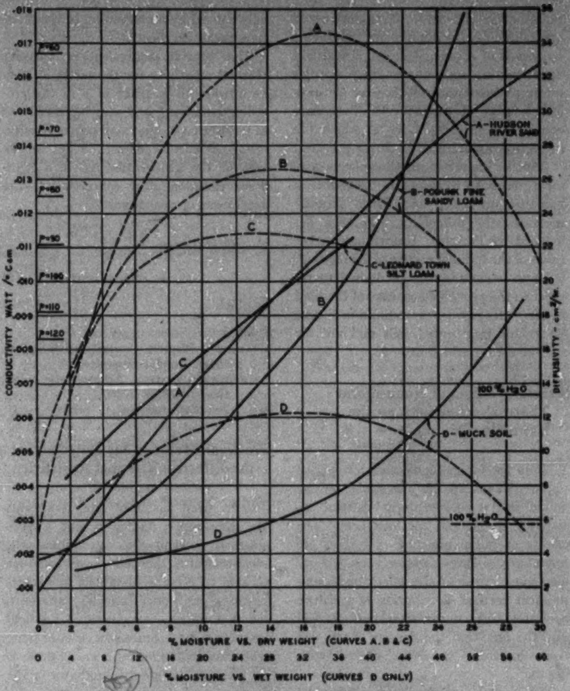

Figure 8. Values of thermal conductivity (solid lines), and diffusivity (dashed lines) of certain fragmented soils at various moisture contents, as given by Patten

thermal resistivity of the soil will depend upon these factors and the amount of capillary water present. It should be evident, therefore, that correct determination of the thermal resistivity indicative of field conditions must involve tests on an undisturbed sample extracted from the field.

This fundamental fact has been disregarded in most laboratory determinations on samples taken from actual cable locations intended to establish the proper value of thermal resistivity for use in the Kennelly formula.

W. O. Smith has investigated the relationship between the thermal resistivity of samples in the natural state and after fragmentation, and his published results on dry soils indicate that the thermal conductivity is higher in the natural state.[4,6] Similar investigations on moist soils have not been published yet, but the differences observed are in the same direction.

Of course, the soil in the vicinity of a new cable installation cannot be considered strictly as virgin soil, but after a period of time, if undisturbed, it will approach this condition, and the above generalization holds: that the thermal resistivities obtained in the laboratory, after the soil has been dug up and then packed into the measuring device, will be higher than those actually pertaining in the field.

There is another effect of major importance which must be considered. Smith[6,7] and others have observed that when moist soils are subjected to a thermal gradient, some of the moisture will move in the direction of heat flow. The amount of such moisture migration is a function of the thermal gradient, and of the moisture content of the sample. This effect is negligible both at the wilt point and at field capacity. For intermediate moisture contents, moisture migration will take place, reaching a maximum at an initial moisture content which has been referred to as the "thermal critical moisture-content."[7]

In our case, this phenomenon will result in a nonuniform thermal resistivity throughout the heat field of the radiator. The increase of the thermal resistivity, above the inherent value for the given conditions of soil and initial moisture content, is progressively less as the distance from the center of the radiator increases, and, practically, is of significance only within relatively short distances from the radiator. This corresponds with the observed higher values of thermal resistivity found near the surface of a sphere, both by the British[11] and those obtained by us in measuring the temperature rise of the earth at points close to the surface of spherical heat radiators.

To solve the problem rigorously from a mathematical standpoint, it is necessary to determine an expression for the variation of thermal resistivity as a function of temperature gradient and initial moisture content, and to introduce this relationship into the basic differential equation from which equations 1, 2, and 3 are derived. (See Appendix I.) This procedure is outlined in Appendix IV, where it will be seen that the resulting solution for the temperature rise at the surface of the radiator is similar to equation 2, with two additional terms which are functions of known parameters, and a moisture migration factor K_m. At the present time, K_m cannot be evaluated too accurately because of the lack of good experimental data. Using the best data available, however, for an 8-inch cylinder dissipating 38 watts per foot and buried to a depth of 40 inches in a soil of 60 degree centigrade centimeters per watt initially, the effect of maximum moisture migration is to increase the temperature rise at the surface of the cylinder by only 5 per cent, although the thermal resistivity at the surface has been increased by 21 per cent. For a radiator three times as large under the same conditions, the temperature rise at the surface is increased only 2.5 per cent with maximum moisture migration, and the thermal resistivity at the surface, by 6 per cent.

It will be apparent that the inherent moisture migration, occurring during laboratory thermal resistivity tests on samples of moist soils, will result in the indication of thermal resistivities higher than those truly representative of the initial moisture content. The magnitude of this discrepancy will vary with the type of equipment and test procedure used, but in most cases it is appreciable in contrast to the relatively small effect cited above for the case of typical cylindrical radiators in the field. Shanklin[8] noted great difficulty in obtaining measurements by means of a concentric cylindrical test apparatus on soils at certain particular moisture contents, which may be presumed to be the thermal critical moisture contents mentioned above at which the moisture migration effect is the greatest.

A rather interesting method of measurement, designed to eliminate the effects of moisture migration and which actually measures the diffusivity, has been developed by Patten.[9] Unfortunately, because of the indirect nature of the method, it leaves something to be desired in respect to the probable accuracy of the final results. His results, reproduced in Figure 8, are for fragmented soils and not for soils in the natural state.

Practical Effect of Nonuniform Thermal Resistivity on the Kennelly Formula

From the foregoing discussion it will be apparent that, in the practical case, we would not expect uniform thermal resistivity throughout the heat field. The effects of radial moisture migration are apparently of minor importance, but we also must consider the effect of a nonuniform vertical distribution of moisture as water sinks down after rainfall, and also the fact that the density of the soil itself increases in some degree with depth.

The solution of the basic differential equation with the thermal resistivity decreasing in some manner with depth presents a mathematical problem of considerable complexity. Nevertheless, attempts are being made currently to effect such a solution. At the present time, we probably are justified in the assumption that the Kennelly formula may be applied involving an over-all equivalent thermal resistivity which is momentarily constant but which, of course, will vary in some degrees seasonally.

It should be noted that, in all of the modifications to the Kennelly formula or alternate procedures of calculation proposed, the assumption of a constant thermal resistivity in the earth has been retained.

While it would be extremely difficult to solve each particular problem otherwise, it does seem desirable to complete the previously mentioned mathematical study, and to conduct a series of carefully controlled and co-ordinated tests to throw further light on this matter, particularly in respect to the limits at which the so-called "runaway" condition commences, and which is undoubtedly caused by an extension of the moisture migration effect.

This over-all equivalent or effective thermal resistivity for the earth, ρ', may be introduced in place of ρ in the preceding equations, and may be considered as including the effects of surface resistivity at the earth's surface. Thus, we obtain for the temperature rise of a cylindrical radiator, after converting to the usual units of measurement

$$T = 0.0120\, Q\rho' \log_{10} \frac{L+\sqrt{L^2-R^2}}{R} \quad \text{degrees centigrade} \qquad (5)$$

in which

Q = heat flow, in watts per foot
ρ' = earth's effective thermal resistivity, in thermal ohm centimeters
L = depth of the center of the radiator below the surface, in inches
R = radius of the radiator, in inches

Practical Methods for Determining the Effective Thermal Resistivity

From what has been said, it appears that laboratory testing is not a very practical method for determining the effective earth thermal resistivities applicable to cable installations in various locations and under seasonal variations, and that direct observations in the field are preferable. Since the use of long cylindrical radiators on a grand scale is not feasible, the spherical radiator or the short cylindrical radiator appears to offer the best compromise.

These test radiators, the equations for which are developed in Appendixes I and III, have the advantage of requiring a minimum amount of trench digging, and have a relatively high attainment factor for relatively short times, see Figure 8. The British have employed such test radiators,[11] and in this country the Philadelphia Electric Company, The Consolidated Edison Company, and The Detroit Edison Company[12] are employing them. Such installations should include the measurements of temperatures of the earth at various short radial distances from the radiator, in order that the moisture migration effect may be studied at the same time.

While the theory presented would predicate slightly different effective thermal resistivities for various values of heat flow, it would appear, in the light of experience, that sufficiently close approximations to the values applicable to long cylindrical radiators will be obtained if the test radiator is operated at the same temperature rise as that expected of the long cylindrical radiator.

Correction for the effect of the attainment factor on the field values obtained for both spheres and long cylinders readily is made by plotting the observed temperature rise at the surface of the radiator against time (with constant heat flow) on log–log paper. The comparable curve from Figure 8 is plotted on a similar sheet. The curve sheets are then superimposed, and the upper portions of the curves are brought into the best alignment, keeping the axes of the two sheets parallel. When so aligned, the 100 per cent attainment factor will fall on the ultimate temperature rise; also, the relationship between t and $t\alpha/r^2$ is established. From this, the effective diffusivity may be determined.

Conclusions

1. The Kennelly formula properly may be used to calculate the ultimate temperature rise of a horizontal cylindrical thermal radiator buried in the earth, with sufficient accuracy for cable-system temperature calculations.

2. The effective thermal resistivity of the earth, which is an inherent part of the formula, must be determined properly for the particular field conditions pertaining.

3. Most laboratory determinations of the thermal resistivity of soils commonly cited, do not represent conditions as faced in practical installations. Corresponding determinations made in the field, by back calculations by the Kennelly formula, will be too low unless correction is made for the time factor involved.

4. The spherical test radiator offers a very practical method for determining the effective thermal resistivity of the soil in which a cable system is to operate.

Symbols

α = thermal diffusivity, in square centimeters per hour
β = thermal surface resistivity, in degree centigrade square centimeters per watt
C_f = field capacity of the soil
d = distance from a point P in the heat field to the thermal center of the radiator, O, in centimeters
d' = distance from a point P in the heat field to the thermal center of the image, O', in centimeters
F = the correction factor for surface resistivity
G_c, G_s = geometric factors which are functions of t, α, and d
h = distance from the thermal center of the radiator or its image to the isothermal plane (surface of the earth)
K_m = moisture migration factor, in watts per degree centigrade squared
κ = thermal conductivity, in watts per degree centigrade centimeter
l = length of a short cylindrical radiator
l' = axial distance of a point P on the surface of a short cylindrical radiator from its center

L = distance from the physical center of the radiator to the surface of the earth
M = moisture content of the soil
ΔM = change in moisture content of the soil
Q_c = heat loss from a long cylindrical radiator, in watts per centimeter
Q_s = heat loss from a spherical radiator, in watts
Q_{sc} = heat loss from a short cylindrical radiator, in watts
r = radius of the radiator, in centimeters
R = radius of an isothermal surface for a cylindrical radiator, and also the radius of a cylindrical radiator where $D > h$
ρ = thermal resistivity, in degree centigrade centimeters per watt
ρ_i = initial thermal resistivity of the soil
ρ_p = thermal resistivity of the soil at a point P in the heat field
ρ' = effective over-all thermal resistivity
T = temperature, degrees centigrade
ΔT = temperature rise above ambient temperature
t = time, in hours
θ = the angle which d' makes with the vertical (See Figure 1)
x, y = rectangular co-ordinates of a point P in the heat field

Appendix I. Temperature Rise of Cylindrical and Spherical Thermal Radiators in a Medium of Constant Thermal Resistivity Bounded by an Isothermal Plane

Assume that a long, straight filament continuously radiating Q_c watts per unit length, is located in an infinite medium of constant thermal resistivity ρ. This location is shown in cross-section in Figure 1 at the point O. The differential equation governing this heat flow as a function of the temperature T at any radius r is

$$\frac{dT}{dr}+\frac{Q_c\rho}{2\pi r}=0 \qquad (6)$$

The temperature rise at any point such as P at a distance d from O is obtained by integrating equation 6 between the limits $r=\infty$ and $r=d$. Thus

$$\Delta T_p=\int_\infty^d -\frac{Q_c}{2\pi r}\rho\, dr \text{ degrees centigrade} \qquad (7)$$

Let us now assume that a similar parallel filament located at point O' continuously is absorbing $-Q_c$ watts per unit length. If the distance of P from O' is d', the temperature rise resulting at P may be found in a similar manner.

If these two heat flows operate simultaneously, by the superposition theorem, the resulting temperature rise is given by

$$\Delta T_p=\int_\infty^d -\frac{Q_c}{2\pi r}\rho dr+\int_\infty^{d'}\frac{Q_c}{2\pi r}\times \rho dr = Q_c\frac{\rho}{2\pi}\log_e\frac{d'}{d} \text{ degrees centigrade} \qquad (1)$$

If, in equation 1, the ratio d'/d be represented by k, and the position of the point P be represented in rectangular co-ordinates, as indicated in Figure 1, then

$$d'^2=(h+x)^2+y^2;\quad d^2=(h-x)^2+y^2 \qquad (8)$$

and, by introducing k, we obtain

$$\left\{x-h\left(\frac{k^2+1}{k^2-1}\right)\right\}^2+y^2=4h^2\left(\frac{k}{k^2-1}\right)^2 \qquad (9)$$

This will be recognized as the equation of a circle of radius

$$R=2h\left(\frac{k}{k^2-1}\right) \qquad (10)$$

whose center lies at a distance below the origin

$$L=h\left(\frac{k^2+1}{k^2-1}\right) \qquad (11)$$

$$L^2-R^2=h^2 \qquad (12)$$

Thus, for various constant values of ΔT_p in equation 1, the locus of point P is a family of eccentric cylinders (circles in section in Figure 1) about the point O if ΔT_p is plus, and about O' if ΔT_p is minus. These isothermal cylinders increase in diameter as the value of $\log d'/d$ (k in equation 10) decreases, and for $\log d'/d=0$, they merge into a plane bisecting and perpendicular to the line O-O'. For all positions of P on this plane, the value of ΔT_p is zero.

If by some means we are able to maintain this plane as an isothermal at zero temperature-rise, it is evident that equation 1 represents the temperature rise of any position of P below the plane, resulting from the heat liberated at point O and regardless of what happens above the plane.

By solving equations 10 and 11 for k in terms of L/R and substituting in equation 1, the following expression is obtained in terms of the radius R of any isothermal cylinder and the depth L of its axis below the isothermal plane

$$\Delta T=Q_c\frac{\rho}{2\pi}\log_e\frac{L+\sqrt{L^2-R^2}}{R} \text{ degrees centigrade} \qquad (2)$$

In the case of a spherical radiator, the radiator and sink are point sources radiating and absorbing Q_s and $-Q_s$ watts, respectively.

$$\frac{dT}{dr}+\frac{Q_s}{4\pi r^2}\rho=0 \qquad (13)$$

and

$$\Delta T_p=\int_{d'}^d -\frac{Q_s}{4\pi r^2}\rho dr=Q_s\frac{\rho}{4\pi}\left(\frac{1}{d}-\frac{1}{d'}\right) \text{ degrees centigrade} \qquad (4)$$

The isothermal surfaces resulting from equation 4 are distorted ellipsoids of revolution merging into a median plane, as in the case of equation 1. For relatively small values of d in comparison to d', the isothermal surface is, for practical purposes, spherical in form and concentric with point O. Thus, equation 4 may be used in determining the temperature rise of a small spherical radiator.

Short cylindrical radiators sometimes are employed as an alternate to spherical test radiators. By considering the heat flow per unit length to be distributed along the axis of the radiator, we can, by integrating a modification of equation 4, determine the temperature rise resulting at any point in the heat field, which may be effectively a point on the surface of the radiator.

Let L be the depth to the center of such a radiator of length l and radius r, and let l' represent the axial distance of a point P on the surface of the radiator from the center and x the axial distance from P of the unit heat source. Thus, from the first term of equation 4, which represents the source portion, we may write by application of the superposition principle

$$\Delta T_p=\int_0^{\frac{l}{2}+l'}\frac{Q_{sc}\rho}{4\pi l}\frac{dx}{\sqrt{x^2+r^2}}+\int_0^{\frac{l}{2}-l'}\frac{Q_{sc}\rho}{4\pi l}\frac{dx}{\sqrt{x^2+r^2}} \text{ degrees centigrade} \qquad (14)$$

The effect of the sink may be developed in similar manner, but, from a practical standpoint, the second term of equation 4 may be employed with negligible error.

It will be noted that ΔT_p will vary with l', the position of the point P along the radiator. Practically, because of the high conductivity of the surface of the radiator, the temperature rise of all points on the surface will tend to equalize. The effect may be cared for by reintegrating equation 14 with l' as the variable. Thus, the complete expression for the temperature rise at the surface of the radiator is given by the expression

$$\Delta T=\frac{2}{l}\int_0^{\frac{l}{2}}\Delta T_p dl'-\frac{Q_{sc}\rho}{4\pi}\frac{1}{2L} \text{ degrees centigrade}$$

$$=\frac{Q_{sc}\rho}{2\pi l}\left[\log_e l/r+\sqrt{(l/r)^2+1}+r/l-1-l/4L\right] \text{ degrees centigrade} \qquad (15)$$

In the usual application, $l=8r$ and $L=4l$, approximately. Under these conditions equation 15 reduces to

$$\Delta T=0.115\frac{Q_{sc}\rho}{l}=0.0144\frac{Q_{sc}\rho}{r} \text{ degrees centigrade} \qquad (16)$$

where l or r is measured in inches.

Appendix II. The Effect of Surface Resistivity at the Isothermal Plane

The heat field in the uniform medium must satisfy Laplace's equation, see Figure 1

$$\frac{\partial^2T}{\partial x^2}+\frac{\partial^2T}{\partial y^2}=0 \qquad (17)$$

The boundary condition at the surface of the cylindrical radiator at the point ($y=0$, $x=h$) is

$$\frac{\partial T}{\partial r}+\frac{Q_c\rho}{2\pi r}=0 \qquad (18)$$

At the isothermal plane of surface resis-

Table I. Values of G_c for a Long Cylindrical Radiator

tivity β ($x=0$), the boundary condition is

$$\frac{\partial T}{\partial y}-\frac{\rho}{\beta}T=0 \tag{19}$$

The solution of equation 17 with the boundary conditions imposed by equations 18 and 19, as developed by Poritsky,[3] takes the form

$$\Delta T_p=Q_c\frac{\rho}{2\pi}\,\mathcal{R}\left[\log_e\frac{d'}{d}-2\epsilon^{\frac{\rho}{\beta}d'}E_i\left(-\frac{\rho}{\beta}d'\right)\right]$$

degrees centigrade (20)

in which $\mathcal{R}$ denotes "the real part of" the following complex expression, d' and d being vectors, and E_i denotes the exponential integral of the expression contained in parentheses.

Equation 20 is readily soluble as it stands for locations of the point P on the line O-O' ($x=0$), since under this condition, the expression contained within the brackets is not complex. For other locations of P, equation 20 may be converted to an asymptotic series in the form

$$\Delta T_p=Q_c\frac{\rho}{2\pi}\left(\log_\epsilon\frac{d'}{d}+F\right)$$

degrees centigrade (21)

where

$$F=2\sum_{1}^{\infty}\frac{-(-1)^n(n-1)!\cos n\theta}{\left(\frac{\rho}{\beta}d'\right)^n}$$

$$=1.90\frac{\beta\cos\theta}{\rho d'} \tag{22}$$

approximately, and θ is the angle between O'-O and O'-P, see Figure 1.

Appendix III. The Temperature—Time Transients of Cylindrical and Spherical Radiators

The Fourier equation for the heat flow from a cylindrical radiator in an infinite medium is

$$\frac{\partial^2 T}{\partial r^2}+\frac{1}{r}\frac{\partial T}{\partial r}=\frac{1}{\alpha}\frac{\partial T}{\partial t} \tag{23}$$

in which α, the thermal diffusivity of the medium, is equal to the reciprocal of the product of the thermal resistivity by the thermal capacitance. It may be shown[10] that the solution of this equation for temperature rise at any point in the heat field, as a function of elapsed time t, may be represented with sufficient accuracy for our purposes by the expression

$$\Delta T_p=\frac{Q_c\rho}{2\pi}\int_{\frac{1}{2}\sqrt{\frac{d^2}{t\alpha}}}^{\infty}\frac{\epsilon^{-\beta^2}}{\beta}\,d\beta$$

degrees centigrade (24)

From the theory of images outlined in Appendix I, for the case of a horizontal cylindrical radiator buried beneath an isothermal plane

$$\Delta T_p=\frac{Q_c\rho}{2\pi}\left[G_c(d)-G_c(d')\right]$$

degrees centigrade (25)

where

$$G_c=\int_{\frac{1}{2}\sqrt{\frac{d^2}{t\alpha}}}^{\infty}\frac{\epsilon^{-\beta^2}}{\beta}\,d\beta \tag{26}$$

The value of equation 26 for various values of $t\alpha/d^2$ is given in Table I.

Figure 7 shows the value, attained by equation 25, for the temperature rise at the surface of the radiator as a percentage of the ultimate temperature rise in infinite time, equation 3, plotted against $t\alpha/r^2$ for several values of the ratio L/r.

Similarly, for a spherical radiator, the Fourier equation for heat flow is

$$\frac{\partial^2 T}{\partial r^2}+\frac{2}{r}\frac{\partial T}{\partial r}=\frac{1}{\alpha}\frac{\partial T}{\partial t} \tag{27}$$

The solution of this equation by operational calculus and the application of the theory of images, where the spherical radiator is buried beneath an isothermal plane, yields the following expression

$$\Delta T_p=\frac{Q_s\rho}{4\pi}\left[\frac{G_s(d)}{d}-\frac{G_s(d')}{d'}\right]$$

degrees centigrade (28)

in which the value of G_s for various values of $t\alpha/d^2$ is given in Table II.

The values, attained by equation 28, for the surface of a sphere having a L/r ratio of 12 as a percentage of the ultimate temperature-rise in infinite time, equation 4, also are shown in Figure 7.

Appendix IV. The Effect of Radial Moisture Migration in the Heat Fields of Buried Cylindrical and Spherical Thermal Radiators

A. S. Mickley[13] has developed the following theoretical expression which checks very nicely with the data determined by Smith[5] on moisture migration in moist soils

$$\Delta M=k_1\frac{dT}{dr}\left[\left(\frac{M_i}{C_f}\right)^2-\left(\frac{M_i}{C_f}\right)^3\right]\text{ per cent} \tag{29}$$

in which ΔM is the change in moisture content per unit volume expressed as a percentage of dry weight per unit volume; k_1 is a constant for the particular soil condition; dT/dr is the temperature gradient across unit radius in degrees centigrade per centimeter; M_i is the initial moisture content, and C_f is the field capacity, both expressed on the same basis.

Since a change in moisture content will result in a change in thermal conductivity, and since the change in moisture content will be relatively small in proportion to the total moisture content, it is justifiable to assume a linear relationship between these changes. Thus

$$\Delta\kappa=k_2\Delta M$$

watts per degree centigrade centimeter (30)

The thermal conductivity of any point in the field is given by the expression

$$\kappa_p=\kappa_i+\Delta\kappa=\frac{1}{\rho_i}+\Delta\kappa=\frac{1}{\rho_p}$$

watts per degree centigrade centimeter (31)

Combining equations 29, 30, and 31, and solving for ρ_p

$$\rho_p=\frac{\rho_i}{1+\rho_i\frac{dT}{dr}K_m}$$

degree centigrade centimeters per watt (32)

where

$$K_m=k_1k_2\left[\left(\frac{M_i}{C_f}\right)^2-\left(\frac{M_i}{C_f}\right)^3\right]$$

watts per degree centigrade squared (33)

The expression within the brackets in equation 33 represents the variation of moisture migration with initial moisture

Table II. Values of G_s for a Spherical Radiator

$\frac{t\alpha}{d^2}$	G_s	$\frac{t\alpha}{d^2}$	G_s	$\frac{t\alpha}{d^2}$	G_s
0.01	0.104	0.70	0.523	40.0	0.912
0.02	0.142	1.00	0.572	70.0	0.933
0.04	0.191	2.00	0.663	100	0.944
0.07	0.240	4.00	0.744	300	0.968
0.10	0.276	7.0	0.799	1,000	0.982
0.20	0.356	10.0	0.829	3,000	0.990
0.40	0.446	20.0	0.877	10,000	0.994

content, and reaches a maximum value of 0.32 at the "thermal critical moisture content." While firm values indicative of the constants k_1 and k_2 are not presently available, Smith's data[5,13] seem to indicate a maximum value of 9.6 per cent centimeter per degree centigrade for k_1. From Figure 9, a representative value of 0.0006 watt per degree centigrade centimeter per cent is indicated for k_2. Thus, the value of K_m for maximum moisture migration effect is in the order of 0.002 watt per degree centigrade squared.

As indicated in Appendix I, the basic differential equation for the heat flow from a cylindrical radiator is

$$\frac{dT}{dr}+\frac{Q_c\rho_2}{2\pi r}=0 \tag{34}$$

Substituting equation 32 in 34 and solving for dT

$$dT=\frac{-1\pm\sqrt{1-A/r}}{2\rho_1K_m}\,dr \quad \text{degrees centigrade} \tag{35}$$

where

$$A=\frac{2}{\pi}\rho_1{}^2Q_cK_m \text{ centimeters} \tag{36}$$

If $K_m=0$ be substituted in equations 35 and 36, the resulting expression is either indeterminate or infinite, according to whether the plus or minus sign is used before the second term of the numerator. Since, under this condition, dT has a finite value, as indicated by equation 34, the plus sign should be used.

Expanding equation 35 into a binomial series and integrating, we obtain the following expression for the temperature rise of a point P in the heat field

$$\Delta T_P=\frac{Q_c\rho_1}{2\pi}\left[\log_e\frac{d'}{d}+\frac{A}{4}\left(\frac{1}{d}-\frac{1}{d'}\right)+\frac{A^2}{16}\left(\frac{1}{d^2}-\frac{1}{d'^2}\right)\ldots\right] \text{ degrees centigrade} \tag{37}$$

By solving equations 32 and 34 simultaneously to eliminate dT/dr, an expression for ρ_p is obtained

$$\rho_p=2\rho_1\frac{d}{A}\left[1-\sqrt{1-\frac{A}{d}}\right] \text{ degree centigrade centimeter per watt} \tag{38}$$

Similarly, in the case of a spherical radiator, the following comparable equations are obtained

$$dT=\frac{-1+\sqrt{1-B/r^2}}{2\rho_1K_m}\,dr \quad \text{degree centigrade} \tag{39}$$

where

$$B=\frac{1}{\pi}\rho_1{}^2Q_sK_m \text{ square centimeters} \tag{40}$$

$$\Delta T_P=\frac{Q_s\rho_1}{4\pi}\left[\frac{1}{d}-\frac{1}{d'}+\frac{B}{12}\left(\frac{1}{d^3}-\frac{1}{d'^3}\right)+\frac{B^2}{40}\left(\frac{1}{d^5}-\frac{1}{d'^5}\right)\cdots\right] \text{ degree centigrade} \tag{41}$$

$$\rho_p=2\rho_1\frac{d^2}{B}\left[1-\sqrt{1-\frac{B}{d^2}}\right] \text{ degree centigrade centimeter per watt} \tag{42}$$

Discussion

W. A. Del Mar (Phelps Dodge Copper Products Corporation, Tarrytown, N. Y.): The author's paper is one of two papers by him which are the culmination of long discussions which have taken place, first in voluminous correspondence between the engineers of cable companies, then in the cable subcommittee of the old transmission and distribution committee of the Institute, and, finally, in the cable characteristics subcommittee of the present committee on insulated conductors. The other paper we hope to see later this year.

The discussion originated in the rivalry of oil-filled cables in ducts and the various types of pressure cables in pipes. The problem was to estimate the relative carrying capacities of cables of the two types. The difficulty arose from the fact that the usual method of estimating the carrying capacity of duct cables makes use of elements of thermal resistance which were derived from measurements made on cables in ducts without taking into account the thermal resistance of the surrounding soil, whereas the carrying capacity of pipe cables is estimated by means of a formula in which the thermal resistance of the soil is an important factor It, therefore, became necessary to ascertain, if possible, what soil resistivity was inherent in the commonly accepted duct constants. Estimates varied over a range of 3-to-1.

The cable characteristics subcommittee undertook to solve this problem. As chairman of the subcommittee, I tried to bring out the various points of disagreement, and, finding that these seemed to be lodged mostly in the minds of manufacturers' engineers, it seemed advisable to give the utility men the job of dislodging the various prejudices and differences of opinion. I counted myself very fortunate in enlisting the interest of Neher, and feel very grateful to him for his painstaking work, and to the Philadelphia Electric Company's engineers for enabling him to devote so much time to it. This has not been simply a matter of doing some mathematics and writing a paper but it has been a continuous tussle with some of the best minds in the industry. This paper has been rewritten several times to meet the keen criticism of committee members. Whether all differences of opinion have been resolved should appear from the discussion to follow.

Mickley's paper[1] is not only a valuable contribution to this subject, but also should be useful to designers of heat pump systems.

REFERENCE

1. See reference 13 of the paper.

F. H. Buller (General Electric Company, Schenectady, N. Y.): Neher has made a valuable contribution to the theory of heat flow from buried cables and pipes.

It might be pointed out that the Kennelly formula, in both the long and the short forms, is well known in British technical literature on buried cables; that Poritsky provided the solution for the effect of soil surface thermal resistivity; that Ingersoll developed the equation for attainment factor, and Mickley developed the one covering the effect of moisture migration. All this is perfectly true. Neher's contribution involved a synthesis of all these solutions, and an analysis which throws a flood of light on the general problem.

To appreciate what Neher has accomplished and what remains to be done, it is necessary to consider the state of the art at the time when he started his work. The Kennelly formula was well known and universally accepted in Britain, but most American engineers seemed to accept it with some mental reservations. Some, in fact, did not accept it at all. Certain engineers contended that the thermal resistance of the earth was equal to that of a cylinder of soil with a radius equal to the depth of burial of the cable; some went so far as to question the validity of the principle of superposition.

This should make it clear that the state of the art was one of considerable confusion until it was clarified by the sort of study and analysis which Neher has presented so ably. To anybody who thinks this was easy I suggest the careful consideration of the following questions which arose during the analysis.

The Kennelly formula leads to the conclusion that all the heat from the cable in the steady state eventually finds its way to the earth's surface, under the conditions on which the formula is based. This conclusion is absolutely correct but by no means obvious. The reason is that, after an infinite time, the average over-all earth surface temperature is actually the coolest within reach.

If we accept the foregoing statement, would the Kennelly formula apply in the practical case where the earth's surface temperature may actually be higher than the cable temperature? The Kennelly formula and the principle of superposition must be combined to answer this one; the engineer who does not accept the principle of superposition is going to have a hard time finding out what happens. However, he need only study Figures 3, 4, and 5 of the paper and the text to discover the right answer.

It might be mentioned that one of Neher's achievements is to make clear how closely the principle of superposition really does apply, and to what extent it is invalidated by moisture migration. His conclusion is that the effect of moisture migration is slight enough to permit the principle to be used.

Although all the heat eventually reaches the surface of the earth in the wintertime, the increase of moisture content and the decrease in soil thermal resistivity with depth undoubtedly will tend to cause more heat to start off in the downward direction than the Kennelly formula would call for. Just how much is very hard to determine exactly.

One formidable obstacle in the path of progress was the British 2/3 factor. The British found that measurements on soil samples made in the laboratory gave a soil thermal resistivity about 50 per cent in excess of that calculated by means of the Kennelly formula from field tests on buried cables. The following points, between them, probably explain the discrepancy:

1. The attainment factor caused by the very high thermal capacity of the earth, which even after 400 hours leaves 15 per cent of the ultimate temperature to be attained in a certain typical case
2. The variation of soil thermal resistivity with depth, due to the approach to the water table, and the presence of solid rock and earth packing
3. The effect of soil disturbance on laboratory samples, and above the cable in the field.

Neher shows that the second point involves a difficult mathematical problem if this effect is to be evaluated numerically. Moreover, it will be necessary to establish some law of variation of soil thermal resistivity with depth to be used in such a solution if it is to be anything but a mathematical exercise. As previously pointed out, it will result in more downward movement of heat than would be expected from the Kennelly formula.

It may be that, if enough data were available, it would be possible to correlate effective soil thermal resistivity with laboratory measurements taken on suitable samples of the soil at the depth at which the cable is buried, and with the law of soil resistivity variation with depth, when and if this law definitely is established.

The latter part of the third point is mentioned incidentally by Neher. It also would involve a very difficult mathematical analysis if a rigorous numerical evaluation were desired; however, a comparatively easy approximate analysis indicates that the action of the cable ditch as a dry drain may possibly account for a 10- to 15-per cent decrease in effective soil thermal resistivity. If this factor is as important as it looks, a good part of the 2/3 factor would be accounted for.

Incidentally, Neher well might sound a word of warning in this connection. If, as he suggests, the soil around the cable ultimately returns to something approximating the virgin state, its thermal resistivity may be expected to rise, perhaps enough to raise the effective over-all thermal resistivity of the earth as much as 10 to 15 per cent as far as the cable is concerned. A test on a recently buried cable thus might give a temporary soil thermal resistivity lower than that which ultimately will exist when the soil has stabilized over a period of years.

An organized group of utility engineers is in the process of obtaining a good deal of soil thermal resistivity data from buried radiators, and also some heat-run data on buried cables in pipes. The publication of such data would be very helpful, since it would contribute materially to the settlement of the vexed question of soil thermal resistivity in general.

M. H. McGrath (General Cable Corporation, New York, N. Y.): Neher has made a valuable contribution to the determination of the current ratings of underground power cables. His critical review of the Kennelly assumption establishes the latter premise as the logical basis for the further development of rational methods of current rating for all the usual types of installation such as duct lay, direct earth burial, and pipe type. By "rational" methods, we refer to ones in which the heat flow path from conductor to earth is broken up into a series of component parts, and the thermal resistance of the individual parts determined separately and then combined. In recent years, there has been a growing tendency in this country to employ a single over-all transfer coefficient or "correction factor" to cover a large number of the component parts of the thermal path. Even though the latter procedure provides what initially may seem to be a simple way out, experience has shown that it ultimately leads to misunderstanding and confusion. Lack of confidence in the applicability of the Kennelly assumption to the problem has been perhaps the most persistent reason advanced in support of the use of such over-all coefficients. Neher demonstrates clearly that there is little if any need for concern on this score.

Neher gives short and long forms of the Kennelly formula. These result in the following expressions for the external thermal resistance of a buried cylindrical structure

$$R_G=\frac{\rho}{2\pi}\log_e\left(\frac{2L}{R}\right)$$

degrees centigrade per watt per centimeter (43)

$$R_G=\frac{\rho}{2\pi}\log_e\left(\frac{L}{R}+\sqrt{\left(\frac{L}{R}\right)^2-1}\right)$$

degree centigrade per watt per centimeter (44)

Equation 43 assumes that the heat flow lines emerge from the geometric center of the structure. Strictly speaking, the heat flow lines terminate at a small distance vertically above the geometric center of the structure. Equation 44 takes this displacement into account. The magnitude of this displacement or eccentricity is given by

$$e=(L-h)=R\left[\left(\frac{L}{R}\right)-\sqrt{\left(\frac{L}{R}\right)^2-1}\right]$$

centimeter (45)

As Neher correctly points out, for most applications of practical interest, the short form can be employed. The magnitude of the error involved in using the short form, equation 43, in place of the long form, equation 44, is evident from Table I of the discussion which gives, for various L/R ratios, the results obtained by the short form in per cent of the values given by the long form.

In practice, L/R is seldom less than 10, and the error introduced by the use of the short form is entirely negligible.

So-called Kennelly formulas have appeared in many technical articles. In some cases, the forms appear at first sight to be at variance with those given by Neher. For example, Whitehead and Hutchings give the following equation[1]

$$R_G=\frac{\rho}{2\pi}\log_e\left[\frac{\sqrt{(L^2-R^2)}+(L-R)}{\sqrt{(L^2-R^2)}-(L-R)}\right]$$

degrees centigrade per watt per centimeter (46)

By rationalizing the term in brackets, it is found that equation 46 is identical to the long form as given by Neher. In other articles, the following formula appears

$$R_G=\frac{\rho}{2\pi}\cosh^{-1}\left(\frac{L}{R}\right)$$

degree centigrade per watt per centimeter (47)

This also is identical to the long form as given by Neher because

$$\cosh^{-1}\left(\frac{L}{R}\right)=\log_e\ \left(\frac{L}{R}\right)+\sqrt{\left(\frac{L}{R}\right)^2-1}\Bigg]$$

Table 1. Comparison of Long and Short Forms

L/R	$\frac{\text{Equation 43}}{\text{Equation 44}}$ per cent
1.5	114
2.0	105
3.0	102
5.0	101
10.0	100

Table II. Results Obtained with Line and Cylindrical Source Assumption

		Temperature Rise, per cent Ultimate	
L/R	$\frac{t\alpha}{R^2}$	Cylindrical Source (Figure 7 of paper)	Line Source (Reference 12 of paper)
2	10	87	88
2	100	99	99
10	10	51	52
10	100	86	87
10	1,000	98	98
100	10	30	30
100	100	51	51
100	1,000	73	73

Mansfield gives the following expression[2]

$$R_G=\frac{\rho}{2\pi}\log_e\frac{R}{e} \text{ degree centigrade per watt per centimeter} \quad (48)$$

Here again, we have an expression which is identical to the long form of Neher because, from equation 45, we can write

$$\frac{R}{e}=\left[\left(\frac{L}{R}\right)+\sqrt{\left(\frac{L}{R}\right)^2-1}\right]$$

Neher's analysis also provides all that is required to take account of mutual heating between adjacent cylindrical structures. Thus, for a group of equally-loaded structures, the thermal resistance R_M caused by mutual heating at a point P, may be written from Figure 1 of the paper as

$$R_M=\frac{\rho}{2\pi}\sum_1^n\log_e\frac{d_n'}{d_n}$$

degree centigrade per watt per centimeter (49)

where d_n and d_n' are defined as:

d_n = distance from the point where the heat flow lines of the nth adjacent structure terminate, to the point P on the structure under consideration

d_n' = distance from the point where the heat flow lines of the image of the nth adjacent structure terminates, to the point P on the structure under consideration

In rectangular co-ordinates, equation 49 from Figure 1 of the paper becomes

$$R_n=\frac{\rho}{2\pi}\sum_1^n\times \log_e\left[\frac{(x+(L_n-e_n))^2+(y-y_n)^2}{(x-(L_n-e_n))^2+(y-y_n)^2}\right]^{1/2}$$

degree centigrade per watt per centimeter (50)

Whitehead and Hutchings give the following expression for the mutual effect at the highest point of any one structure in the group[1]

$$R_M=\frac{\rho}{2\pi}\sum_1^n\log_e\left[\frac{(L_1+L_n-R)^2+y_n^2}{(L_1-L_n-R)^2+y_n^2}\right]^{1/2}$$

degree centigrade per watt per centimeter (51)

where

L_1 = axial depth of structure considered, centimeters

L_n = axial depth of each other structure of group, centimeters

R = radius of cylindrical structure, centimeters

Y_n = horizontal axial distance between structure considered and each other structure in group, centimeters

This equation follows directly from equation 50 if the heat flow lines are assumed to terminate at the geometric centers, in which case the eccentricity becomes zero.

A further expression which has been suggested takes the form

$$R_M=\frac{\rho}{2\pi}\sum_1^n\log_e\left[1+\left(\frac{2L_n}{y_n}\right)^2\right]^{1/2}$$

degree centigrade per watt per centimeter (52)

This form follows directly from equation 51 on making the assumption that all structures are buried at the same depth, and by using that isothermal of the nth structure, which passes through the axis of the structure under consideration in place, of the isothermal passing through the highest point.

Simmons suggests the following expression for the mutual thermal resistance[3]

$$R_M=\frac{\rho}{2\pi}\sum_1^n\log_e\left(\frac{2L_n}{y_n}\right)$$

degree centigrade per watt per centimeter (53)

This equation follows directly from equation 52 on making the assumption that the horizontal axial spacing between structures is small in comparison to twice the depth of burial. However, if the axial spacing should be greater than twice the depth of burial, use of this approximation results in a negative term, implying a cooling instead of a heating effect.

It is of interest to compare the attainment factors for cylindrical radiators as given by Neher in Figure 7 of the paper with those obtained using the somewhat simpler solution outlined elsewhere[4] for a continuous line source of constant strength. Table II of the discussion indicates that, for the range covered by Figure 7 of the paper, the line source assumption gives results closely equal to those obtained with the cylindrical source assumption.

3. CALCULATION OF THE ELECTRICAL PROBLEMS OF UNDERGROUND CABLES. D. M. Simmons. *Electric Journal*, (East Pittsburgh, Pa.) volume 29, 1932, page 398.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): The author is to be complimented for his patience in investigating this subject and for his ingenuity in developing new thoughts. The Association of Edison Illuminating Companies' cable engineering section, of which I am chairman, is very appreciative of Neher's efforts. The section also has been stimulating field tests on pipe-type cables to obtain a more complete picture for the industry of the variations that occur in thermal properties for different types of installations. The section has been promoting the idea of the reports on findings by utilities being made available to all concerned through the AIEE.

The author has indicated that, in 400 hours of continuous heating, the attainment of the ultimate temperature rise of the earth around the pipe is 85 per cent of the ultimate value. This is quite interesting to C. A. Bauer and me in connection with our activities in Chicago, because we have been assuming that the attainment at that time would be about 95 per cent.

We are obtaining further data in connection with this problem through tests being made on seven 20-foot lengths of pipe that are buried in different types of soil and at different depths. Heating elements are inserted in the pipes and the temperatures on the surface of the pipe will be varied. Furthermore, the tests will include determining effects of continuous heating as against heating part of the time each day.

In the second part of his conclusion, the author speaks of the "effective thermal resistivity of the earth." We have found over the years that, in some cases where conduits develop high temperatures, there seems to be an especially high temperature gradient develop in the earth adjacent to the conduit; this high gradient, usually associated with rather poor types of soil from the thermal standpoint, can be greatly reduced by replacing the soil immediately around the conduit with sand and small gravel. Likewise, with pipe installations in earth where the soil immediately adjacent to the pipe may develop a high thermal gradient incidental to heating to calculated temperature of, say, 70 degrees centigrade, it seems to us that the layer of earth around the pipe may have a much higher thermal resistance than the balance of the earth. Not only do we recognize this in the calculations, but, for one installation of buried cables that was under consideration, we would have made a change in the earth. In that case we would have substituted several inches of sand and small gravel for the earth at the location involved, that earth being in the nature of a heavy clay.

Frank V. Smith (Sargent and Lundy, Chicago, Ill.): Neher has contributed an important paper which should be of great service to the industry. It puts together in a very satisfying form the basic theory of the heating of buried cables and pipes. The methods of taking care of surface resistivity, moisture movement, and transient conditions represent important additions to the literature.

The industry will look forward to the results of the tests being carried out by several of the operating companies on the thermal resistivity of the soil in place by means of spherical or cylindrical radiators, particularly if a comparison can be made between the results obtained by this method and tests carried out in the laboratory with samples of soil.

One point of interest is the temperature rise produced by one cable or pipe on adjacent cables or pipes. The superposition method which Neher has used throughout is an important contribution to the understanding of the way in which heat flows in the earth and can be applied to this problem.

Figure 6 of the paper shows that, for a cable placed $10r$ below the surface, at the end of an infinite time the temperature rise at a horizontal distance $10r$ from the cable is 27 per cent of the temperature rise at the surface of the cable. At a distance of $5r$, it is 47 per cent. If this is translated into the effect on the current-carrying capacity of two similar cables which are to attain the same total surface temperature, it will be found that two cables located $10r$ apart must have their watts loss reduced to 79 per cent of the value for a single cable, and at a distance of $5r$, to a value of 68 per cent of a single cable. If this procedure is extended to the thought of a concrete duct run in which r is the equivalent radius of a group of ducts of perhaps 1 foot or more, it will be seen that the effect of a second duct run spaced 5 or 10 feet away is greater than has been generally considered.

H. B. Dwight (Massachusetts Institute of Technology, Cambridge, Mass.): The flow of electric current into the ground from a buried horizontal cylinder, such as a buried ground wire or counterpoise, and the flow of heat from a buried cable or duct bank might seem at first glance to be similar problems, to be calculated by the same formulas. However, they are not the same, as is shown admirably by J. H. Neher in this paper.

Since air is an insulator to electricity, there is no flow of electric current across the ground surface, which is a flow line in the current flow map. In winter, the heat from a duct bank flows rather directly to the ground surface and crosses it practically at right angles, as in Figure 4 of the paper. In summer, the interest is in the hottest condition, for determining the power rating of the duct bank, and the ground surface may be hotter than the temperature around the duct bank. The flow of heat from the duct bank at such a time is into the ground and not up to the ground surface. The mathematical solution for electric current flow into the ground nevertheless should not be used. There is still heat flow either into or out of the ground surface.

It is much better to use the method of Neher's paper, in which the heat flow is divided into two components, one being the heat from the duct bank, assuming it to be the only source of heat, and the other being the heat to or from the ground surface when the duct bank is considered absent. The solutions for heat flow and temperature rise for the two components can be superposed. That is, for any time of year, equation 1 or 1*a* gives the temperature rise of the surface of the buried cylinder, or other point, above what the temperature would be if there were no cylinder.

For testing purposes, a small sphere would seem to be better than a short cylinder, since there is a reliable formula for resistance to ground of the sphere by which a temperature measurement can give a direct determination of earth resistivity. Since the escape of heat from the buried object is entirely by conduction, there may be some question about calling it a radiator.

If measurements are to be made comparing the heat flow from small finite objects, such as spheres and short cylinders, to the surrounding material, which is a geometrical problem, it would seem better to take advantage of the established precise type of measurement of the flow of electricity from a metal object to a liquid in which it is immersed. The direct measurement of thermal resistivity of the earth would, of course, have to be made by the more uncertain measurement of heat flow in the earth, and the most favorable shape of metal object then could be used.

The use of equation 22 to account for the ground surface resistivity seems to be more of a complication than is needed. The loss of heat from the ground surface is approximately proportional to the temperature rise of the ground above the air. This is the assumption made for deriving equation 22 where the surface resistivity is taken to be a constant, β. The usual formulas for emission of heat from a warm surface have a result the same as if the surface were covered with a layer of undisturbed air about 1/4 to 1/2 centimeter thick. The outer surface of the layer is taken to be at the ambient air temperature, and the transfer of heat is taken to be by conduction only. Since a layer of undisturbed air has a resistivity of 3,800 degrees centigrade for one watt through one centimeter cube at 25 degrees centigrade, this would mean a surface resistivity of $\beta = 1/2 \times 3{,}800 = 1900$ degrees centigrade for one watt through one square centimeter, if the layer is taken to be 1/2 centimeter thick.

If ρ for the earth is 60, and β is 2,000, as given in the paragraph following equation 1*a* of the paper, then the layer of air is equivalent to a layer of earth of thickness

$$\frac{2000}{60} = 33 \text{ centimeters}$$

which is 13 inches, or 1.1 feet.

This would mean that the flow of heat and the temperatures may be computed as if 1.1 feet, or less, of earth were added at the top of Figures 3 and 4; that is, the cylinder would be at a depth of 5.1 feet instead of 4 feet. Since 1.1 feet is small compared with other dimensions in Figures 3 and 4, the flow lines through the added layer of earth would be almost straight and vertical, and there does not seem to be need to use a 2-layer calculation. The computation made by adding a layer of earth at the ground surface is especially desirable since the second term in equation 1*a* is the approximate sum of an infinite series, the convergence of which is unsatisfactory because of the presence of $(n-1)!$ in the numerators of the terms.

W. A. Hadley (Columbia University, New York, N. Y.): I think Neher is to be commended on his excellent paper. It explains many of the discrepancies previously noted between laboratory and field test data with regard to the Kennelly formula. To the best of my knowledge, it is also the first paper to evaluate the effect of moisture movement on heat transfer in soils.

I am in agreement with Neher's conclusion that thermally-actuated moisture migration is a minor consideration with respect to buried cables. In this instance the loss of moisture around the cable probably is small, and the attendant thermal effects likewise will be small.

However, in the reverse case, where a buried pipe acting as a thermal receiver is being considered, as in a heat-pump ground coil, the effects of thermally-actuated moisture migration may be significant. With a heat sink, the moisture migration is toward the pipe, which will saturate the soil around the pipe. In fact, if freezing conditions exist around the pipe, it is possible for the moisture to be trapped by freezing and to produce a moisture concentration greater than saturation. As varieties in moisture content may cause a tenfold increase in thermal conductivity, according to certain published data, this is very significant.

In fact, recent studies I have just completed on some heat-pump ground-coil data, in which I used essentially the method of Neher, much closer agreement was obtained between the calculated values and the field-test data when moisture migration was included than when constant properties were used. Unfortunately, there has been very little work done on moisture migration in soils.

J. H. Neher: I am greatly indebted to Del Mar for explaining why this somewhat mathematical exposition has suddenly appeared on the cable scene, and also to Buller for indicating some of the difficulties met with in its preparation. In approaching the practical problems of cable-in-duct installations, which, as Del Mar has indicated, occasioned this study and which will be the subject of a forthcoming paper, I felt that it was highly desirable to first review and obtain an agreement on the fundamental principles underlying the calculation of the temperature rise of buried thermal radiators.

Also, I wish to thank McGrath for his demonstration that the various versions of the Kennelly formula appearing in the literature are directly reducible to the form which I have chosen to use. It is assuring to note too, that the Ingersoll solution for the earth long-time transient which I have employed, is checked by the French formula[1] as cited by McGrath, as well as by the British formula.[2]

Halperin has discussed the attainment factor of 85 per cent given in the paper for a particular pipe-type cable installation after 400 hours. It may be of interest to demonstrate more fully how this may be obtained by graphical means. The upper curve of Figure 1 of the discussion shows the measured temperature rise—time transient plotted on a log-log scale. The points spotted are those measured at the times indicated. Actually the curve was first drawn on rectangular co-ordinates on the basis of many more test points than actually are shown.

The lower curve of Figure 1 of the discussion represents the theoretical temperature rise—time transient, taken from Figure 7 of the paper and plotted to the same log–log scale. By superimposing this curve upon the test curve as shown to obtain the best fit, we establish the ultimate temperature rise as 41 degrees centigrade, and, incidentally, the apparent value of the diffusivity of the earth. In this case the attainment factor after 400 hours is 80 per cent, whereas the 85 per cent figure cited in the paper was obtained from the best fit with the diffusivity (lateral position of the theoretical curve) pegged at 25 square centimeters per hour.

As Halperin points out, especially high thermal gradients may develop in the earth

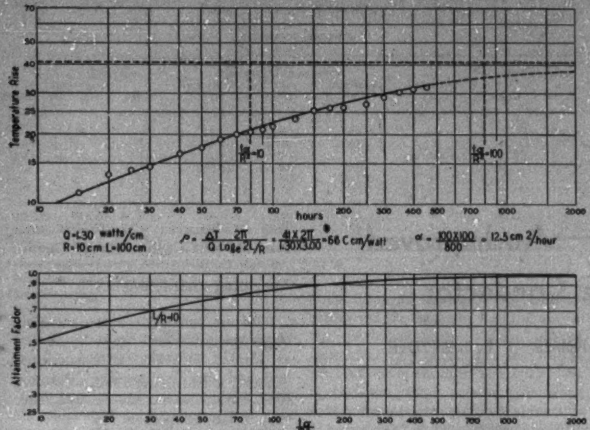

Figure 1. Measured and theoretical temperature—time transients

adjacent to the conduit; this is indicated by the theory presented. It is difficult, though, to understand how this condition may be improved by the substitution of sand or gravel in this region since, like earth, they have relatively high thermal resistivities when dry. What we really need is a material of low inherent thermal resistivity or one which more effectively will retain its moisture against the migration effect discussed. Bentonite clay has been suggested in connection with heat-pump ground coils, and its use may offer some advantages in cable applications.

The use of an "effective thermal resistivity" is admittedly an approximation intended to round out these effects and those resulting from nonuniformity with depth, as discussed by Buller. When and where these effects may be evaluated more fully for a particular critical installation, they should be taken into account. As Buller points out, the drainage-ditch effect of a new installation may outweigh the inherent increase in thermal resistivity of the disturbed soil, with the net result that, as the soil returns slowly to its virgin state, the effective thermal resistivity of the installation may rise.

As Smith has pointed out, the effect of adjacent cables or duct banks on the temperature rise of the particular system under investigation often may be greater than generally is supposed. This effect is calculated readily by use of equation 1 of the paper.

I am very glad that Dwight has mentioned the so-called Rudenberg formula for the electrical resistance of grounded conductors, because this formula has been cited incorrectly in text books and articles as applying to thermal flow as well. Dwight has explained nicely why the electrical formula is not applicable in this instance. As he points out, my use of the word "radiator" is not strictly accurate, but probably is no less so than the application of this term to the modern household article.

I feel that the method of caring for surface resistivity effects at the earth's surface suggested by Dwight is a definite simplification and improvement over the method presented, and suggest that it be used instead whenever such a correction is necessary.

Hadley mentions the effect of moisture migration in the case of a heat-pump ground soil. In this connection I should like to point out that the equation showing the effect of moisture migration on cable temperature rise given in the paper is not reversible. This is because in its derivation the effect of moisture moving outward in increasing the initial moisture content at a given radius is negligible because of the rapidly increasing volume per unit of radius, and may be neglected. With moisture moving inward, however, this effect is appreciable and must be considered. From what we have observed on our own heat-pump installations, and from Hadley's analysis of Coogan's tests, we believe that the practical result is to saturate completely the earth around the ground coil. From the point of view of cable engineers, it is indeed unfortunate that this moisture migration effect is not just the opposite.

Hy-Therm Copper—An Improved Overhead-Line Conductor

L. F. HICKERNELL
FELLOW AIEE

A. A. JONES
MEMBER AIEE

C. J. SNYDER
ASSOCIATE AIEE

THE SIZE of conductors for overhead lines generally is selected on the basis of obtaining the required voltage regulation and most economical power loss. Usually, these criteria result in a larger size than would be necessary from a thermal limitation. Indeed, many transmission text books and reference books do not even consider thermal limits of conductors.

On the assumption that copper anneals at 100 degrees centigrade, continuous current-carrying capacities of hard-drawn copper conductors using a maximum temperature below this value and under various operating conditions have been published as, for example, those shown in Table I.

Wartime conditions have focused attention on the determination of both the maximum continuous and short-time emergency overload capabilities of the conductors. Papers have been published which present methods of calculation considering these conditions.

Recent meetings[14–17] and papers [18–25] have pointed out the need for certain data, up to now unavailable, which are required to accurately determine current ratings for overhead-line copper conductors. Attention was directed specifically to:

1. The effect of noncuprous elements on the annealing characteristics of commercial copper conductors.[19–23] This may be considered in two parts: the effect of silver; and the effect of other constituents (including oxygen).

2. The effect of heat and time (annealing characteristic) on the strength of the conductor.[19–24]

3. The effect of initial hardness and tensile strength on the annealing characteristic.[19] This involves the influence of manufacturing technique; such as, size of hot-rolled rod, number of draws, reduction per draw, intermediate anneals, and so forth.

4. The effect of intermittent heating on the annealing characteristic.[19,23]

5. The effect of tension applied to the conductor on the annealing characteristic.[19–22]

6. The effect of vibration on the annealing characteristic.[19,23]

7. The correlation between change in elastic limit with ultimate strength.[21,24]

8. The effect of wire movement while hot on the annealing characteristic.[21]

In March 1943, following an informal conference,[26] an investigation was initiated to obtain the answers to some of these questions.

Hy-Therm Copper

A new brand of copper has been developed by the Anaconda organization which has improved annealing characteristics permitting higher current loading. It is produced by adding minute amounts of hardening agents to very pure electrolytic copper. This brand of copper due to its controlled composition, has consistently uniform properties. The types and amounts of added material are so chosen that their effect on purity and conductivity are negligible, as shown below:

	Hy-Therm Typical Values	ASTM *B5–43* Specified Minimum
Copper (including silver), per cent	99.953	99.900
Conductivity at 20 degrees centigrade, per cent of international annealed copper standard	100.9	100

For identification, this new copper has been trade-named "Hy-Therm" and branded "*AHT*" (*A*naconda *Hy-T*herm).

Annealing Characteristics

Data are presented on the annealing characteristics of hard-drawn copper wire as affected by chemical composition; heat and time—no tension; heat and time—with tension; intermittent heating; and manufacturing technique.

Effect of Chemical Composition

Data on the effect of various noncuprous elements (metallurgically referred to as "impurities") common to commercial brands of copper were published some years ago. More recently, the effect of iron, nickel, cobalt, silver, cadmium, tin, antimony, and tellurium on the conductivity and softening point of pure copper was covered excellently by Smart and Smith.[27,28] The effect on the annealing point of each element, both with and without oxygen, was shown. Since the effects of various elements on annealing are known to be not additive, and since some elements, especially oxygen, counteract the effect of others, the application of these data to commercial brands of copper containing various small amounts of each of 8 or 10 different elements becomes a difficult problem.

In 1940, for manufacturing purposes a study was conducted of the chemical, electrical, and annealing properties of 21 different brands and/or grades of commercial copper. Table II shows a summary of the chemical composition and conductivity found in common commercial wire-bar copper.

The complexity of correlating chemical composition, usually involving 11 variables, with annealing data made it impossible to draw very definite conclusions.

Paper 49-3, recommended by the AIEE transmission and distribution committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted October 18, 1948; made available for printing November 19, 1948.

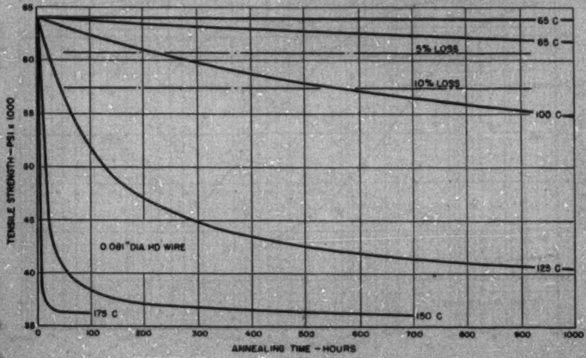
Figure 1. Effect of heat and time—no tension

Brand *B*—hard-drawn wire



Some elements appeared to counteract others and the extremes were not always the controlling factor. "Lake" copper containing 7.67 ounces per ton (0.0253 per cent) silver annealed at a much lower temperature than another containing only 0.48 ounce per ton (0.0016 per cent). However, the sample lowest in silver (0.00016 per cent) was the easiest to anneal. Oxygen content had no noticeable effect on annealing. One oxygen-free copper was near the highest and another near the lowest of the group. The sample highest in antimony and arsenic was also the most difficult to anneal, but other samples of comparatively moderate antimony and/or arsenic content were also difficult to soften. Here again, however, the samples lowest in antimony and arsenic were the fastest to anneal. Nickel had no outstanding effect.

In correlating these annealing data with those from other tests, it was noted that fairly consistent results were obtained on copper from the same refinery brands. It, therefore, appears that the annealing characteristics of copper depend on a particular combination of elements which originates in one particular ore or mine, and which has been refined by a specific routine. The curve of the effect of silver, Figure 3, shown by Seelye and Malmstrom[20] would not apply to commercial copper unless, perhaps, all other elements were held constant. Likewise, their curve for the effect of oxygen, Figure 4,[20] would apply only if other elements such as iron were present, in which case the element would be oxidized and its effect reduced by the presence of oxygen.

Since the chemical composition or annealing characteristic of an overhead-line conductor are likely unknown to the operating engineer, current ratings should be based upon data obtained on commercial brands and/or grades of copper used in the industry.

Accordingly, based on previous investigations of manufacturing process anneals, three brands of copper were selected for this series of long-time, low-temperature tests which would produce annealing ranges as follows:

Brand *AHT*—Hy-Therm copper (having highest resistance to annealing).

Brand *B*—Representative commercial copper.

Brand *C*—Very pure copper (having lowest resistance to annealing).

EFFECT OF HEAT AND TIME—NO TENSION

The annealing characteristics of three brands of copper in the form of hard-drawn wire under no tension are shown in the following figures:

Figure 1—Brand *B* (rectangular co-ordinates).

Figure 2—Brand *C* (semilog co-ordinates).

Figure 3—Brand B (semilog co-ordinates).

Figure 4—Brand *AHT* (semilog co-ordinates).

In Figure 1, data are plotted on rectangular co-ordinates which give the true mental conception of the temperature-time (annealing) characteristic. Annealing starts as soon as heat is applied and progresses at a rate depending upon the temperature until the wire approaches a soft recrystallized state. However, in order to present data for long periods of time, it has been necessary to use a log scale for the annealing time (abscissa) in the remaining figures. It is hoped that this expedient will not lead to the erroneous impression that the wire resists softening for a certain period of time after which it suddenly and rapidly anneals.

Figures 2, 3 and 4 show that 5 per cent loss in strength occurs at various annealing temperatures at the times listed in Table III.

Figure 5 shows a comparison of the annealing characteristics of hard-drawn wire

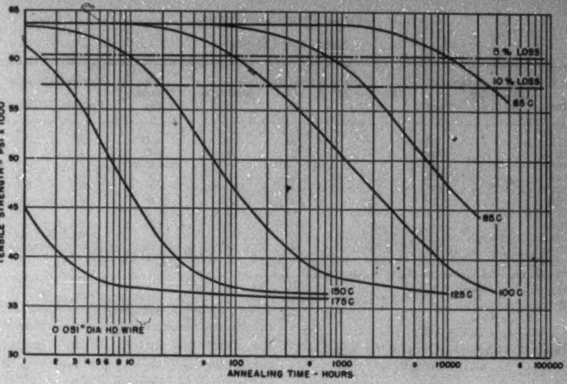


Figure 2 (top). Effect of heat and time—no tension

Brand C—hard-drawn wire

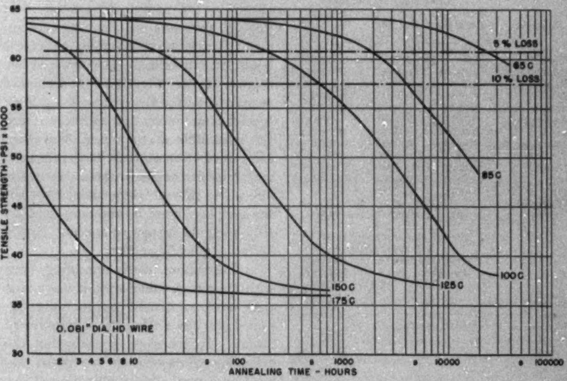

Figure 3 (center). Effect of heat and time—no tension

Brand B—hard-drawn wire

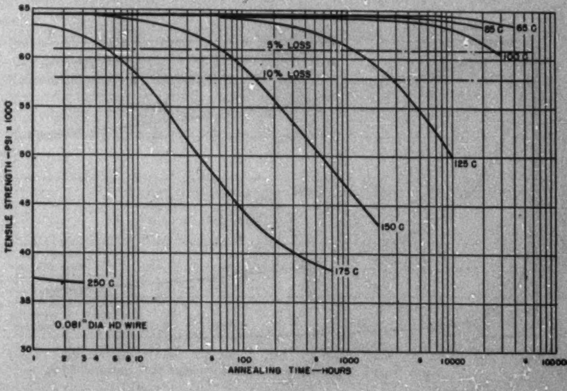

Figure 4 (bottom). Effect of heat and time—no tension

Brand *AHT*—hard-drawn wire

for the three brands at the lower operating temperatures (65, 85, 100, 125 degrees centigrade).

Comparing these data with those published previously, it would appear that previously available commercial copper wire anneals at a lower temperature than indicated by Seelye and Malmstrom,[20] Olmstead[24] and George;[25] also that extrapolating the data of Pilling and Halliwell[29] to temperatures below 100 degrees centigrade is not permissible.

Figure 6 shows a comparison between the authors' data and that of Seelye and Malmstrom (Figure 2)[20] for the time required at different temperatures for a 5 per cent loss in strength for hard-drawn wire. Fortunately, there appears to be some temperature at which no annealing will occur. If this be true, the data for 60 and 47.5 degrees centigrade shown by Olmstead (Figure 7)[24] appear questionable for representative commercial copper, and certainly so for Hy-Therm copper.

EFFECT OF HEAT AND TIME—WITH TENSION

Duplicate samples were heated at 150 degrees centigrade while held under tension equal to 25 per cent of the original breaking strength of the wires. This corresponds to normal working tension in overhead-line operation.

Figure 7 shows the effect of tension on the 150 degrees centigrade annealing

Table III. Temperature/Time Relation

For Five Per Cent Loss in Initial Strength

Annealing Temperature, Degrees Centigrade	Annealing Time for 5 Per Cent Loss in Strength Hard-Drawn Copper Wire Brand *AHT*, Hours	Brand *B*, Hours	Brand *C*, Hours
65	(a)	24,000	10,500
85	(a)	1,950	770
100	24,000	200	95
125	1,100	15	9.5
150	63	2.3	1.4

(a) Indeterminate to date; 1.4 per cent loss in strength occurs in 40,000 hours at 65 degrees centigrade and 21,000 hours at 85 degrees centigrade.

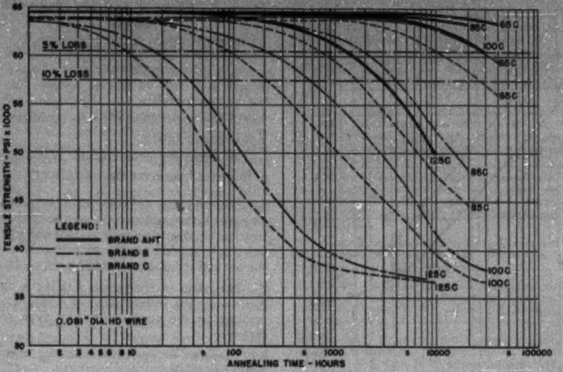

Figure 5. Effect of kind of copper—no tension

Hard-drawn wire

characteristic for hard-drawn wire of brand *B* copper. The rate of annealing is noticeably increased by the application of tension. Under the conditions stated, the reduction in annealing time is approximately 50 per cent. At lower annealing temperatures, it is expected that this effect would be considerably less.

It has been stated in the past[20,24,29] that the annealing rate, or recrystallization, of copper wire increases with increase of hardness caused by cold drawing. If cold drawing were considered as producing internal stresses in the wire in proportion to the total reduction of area after the last-process anneal, and if any external tensile stress on the wire were considered as adding algebraically to the internal stresses, the effect of both temper and tension is to anneal the copper wire at a rate proportional to the total stress in the wire.

Effect of Intermittent Heating

Duplicate samples were heated only eight hours out of each working day in the constant temperature oven used for all 125 degrees centigrade tests.

In Figure 8, the 125 degree centigrade continuous heating curve is reproduced (from Figure 3) and the values obtained on the intermittent heating cycle are plotted.

In four different sets of tests, the effect on annealing was directly cumulative in proportion to the number of hours heated.

Effect of Manufacturing Technique

It is probable that different manufacturing technique would have a small effect on the annealing characteristics of copper wire. Different routines would have an effect on the grain size and the final temper of a wire which, in turn, would be reflected in its annealing characteristic. In general, a fine-grained wire will work-harden faster and anneal at a lower temperature than a coarse-grained wire.[20]

However, the routines for drawing the common sizes and temper of commercial copper wire are so standardized that little variation from this source will be found. Commercial bare wire is produced to specifications which allow little leeway for variations in the manufacturing operations. Weatherproofed wire might show some variations due to the mechanical working and saturating processes.

Table IV. Increased Current Ratings Using Hy-Therm Copper

Conductor Size, (American Wire Gauge or Thousands Circular Mils)	Current Rating Commercial Brands, 75C (Amperes)	Current Rating Hy-Therm (Brand *A HT*), 100C (Amperes)
Solid		
6	120	145
4	165	195
Stranded		
2	230	270
1–0	305	365
2–0	355	425
3–0	415	490
4–0	480	570
350	665	790
500	835	995

Basis:

Method of calculation—Schurig and Frick (*General Electric Review*, March 1930, page 141).

Ambient temperature—25 degrees centigrade.

Air velocity—2 feet per second (1.36 miles per hour), crosswise.

Conductor resistance—96.16 per cent IACS conductivity (ASTM *B1–47*). D-c resistance increased 2 per cent for stranding and converted to operating temperature. A-c resistance determined by Bwan method (*General Electric Review*, April 1930, page 249).

Conductor surface—average tarnished.

Current Ratings

The data presented herein will enable the operating engineer to determine more accurately the thermal limit for existing and future lines based upon his local conditions (relation of peak load to ambient temperature, expected coincidental wind velocity, and so forth).

Continuous Loading

For design purposes, a thermal limit of 75 or 80 degrees centigrade has been used

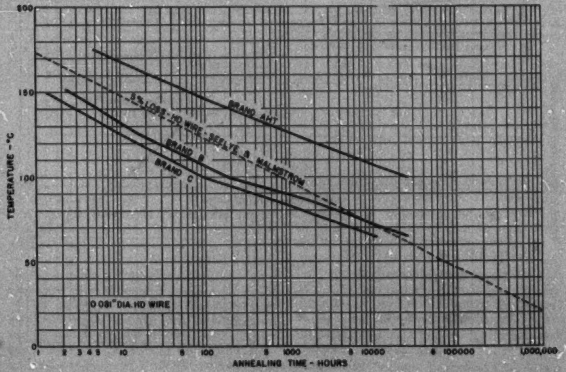

Figure 6. Comparison of annealing characteristics for 5 per cent loss in strength—no tension

Hard-drawn wire

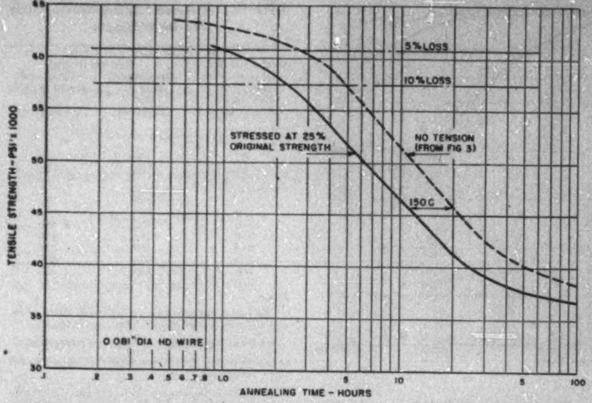

Figure 7. Effect of heat and time—with tension

Brand *B*—hard-drawn wire, 25 per cent original strength

for the commercial brands of copper available previously. These data indicate that hard-drawn copper wire made from these brands will undergo some loss in strength due to annealing even at these operating temperatures. Since no known adverse experience has resulted from ratings based upon these temperatures, it is concluded that under actual operation, these temperatures have not been obtained for a sufficient time to produce annealing due to atmospheric conditions (such as wind velocity) being more favorable than those upon which the ratings were based.

If it is accepted that maximum operating temperatures of 75–80 degrees centigrade have been satisfactory, on an equivalent annealing basis, Hy-Therm copper could be rated at 115 degrees centigrade. However, since it is probable that future lines will be designed to closer operating limits than formerly, it is suggested that a more conservative value of 100 degrees centigrade be selected.

Increasing the permissible maximum continuous operating temperature to 100 degrees centigrade will result in a substantial increase in current-carrying capacity, as shown in Table IV.

SHORT-TIME EMERGENCY LOADING

For commercial hard-drawn copper wire, manufactured to meet the requirements of American Society for Testing Materials specifications, the annealing characteristics are related primarily to the chemical composition of the brand of copper from which it is manufactured.

Brand *B* is representative of the commercial brands of copper more commonly used for overhead-line conductors.

Accordingly, for existing lines, in lieu of actual data on the brand used, it is suggested that short-time emergency current-rating calculations be based upon the annealing characteristics of brand *B* and consideration of local atmospheric conditions (ambient temperatures, wind velocities, and so forth) as proposed by others.[18,20,23,24]

For lines using Hy-Therm copper, these ratings will, of course, be much higher, since, for a given time, the annealing temperature is much higher.

Summary

A new brand of copper has been developed which, by virtue of increased resistance to annealing, permits higher current-carrying capacity and longer useful life under load with no significant loss in conductivity.

The annealing characteristic of copper is influenced by a number of factors:

1. The effect on annealing of noncuprous elements is the resultant of a complex interrelationship due to many variables and the net result appears to depend primarily on the ore and refining processes.
2. The effect of continuous heating is to start annealing immediately at a rate depending on the temperature and type of copper.
3. The effect of intermittent heating is directly cumulative.
4. The effect of externally-applied tension is to increase the rate of annealing.

These data enable continuous and short-time current-carrying capacities of overhead lines to be calculated more accurately.

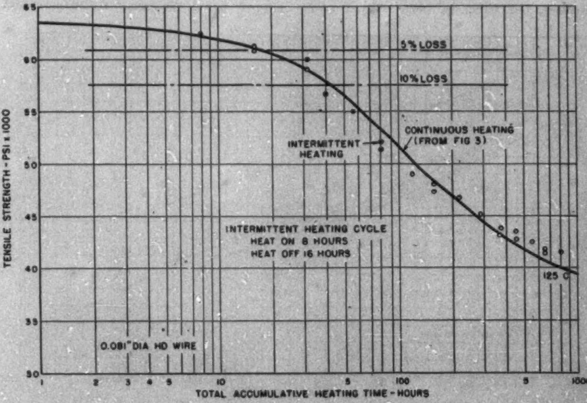
Appendix—Test Procedure

Specimen Preparation

Three sets of wire samples were prepared from three 250-pound wire bars, one each of brands *AHT*, *B* and *C*. Each bar was hot-rolled to 5/16-inch diameter and the rods processed to 0.081-inch diameter hard-drawn wire.

Figure 8. Effect of intermittent heat and time—no tension

Brand *B*—hard-drawn wire



Annealing Without Tension

Tests were made at temperatures of 65, 85, 100, 125, 175 and 250 degrees centigrade by inserting a large number of duplicate 18-inch lengths of wire in a heating medium or oven and withdrawing two test pieces at scheduled intervals. Circulating-air ovens controlled within ±1 degree centigrade were used for the 65 to 125 degree centigrade tests. An oil bath controlled within ±2 degrees centigrade was used for the 150 and 175 degrees centigrade tests. A salt-bath tempering furnace controlled within ±5 degrees centigrade was used for the 250 degrees centigrade tests.

Annealing With Tension

In a circulating-air oven with a 32-inch effective heating length, duplicate samples were heated at 150 degrees centigrade controlled within ±1 degree centigrade while held under tension by calibrated springs. The springs were designed so that 1/16-inch extension exerted 1-pound pull at the working tension. Each spring was calibrated in a tensile-testing machine. The wires were threaded through closely-fitting holes in the ends of the oven and were fastened to a frame with the springs outside the oven. The oven was loaded with 12 samples and one sample withdrawn for test at scheduled intervals. A tension equal to 25 per cent of the original breaking strength of the wires was maintained throughout the tests.

Tensile-Testing Machine

Tensile-strength tests were made on a Southwark Tate-Emery testing machine having a 600-pound dial range reading in 0.5-pound divisions. The samples were pulled at a loading rate of 200-pounds-per-minute unless it was indicated that they were sufficiently annealed that an increase in testing speed had little effect on the results.

Discussion

Engineers of Bonneville Power Administration (Portland, Oreg.): The authors describe a new brand of copper called "Hy-Therm" which appears to have improved annealing characteristics, permitting higher current loadings.

The Bonneville Power Administration generally uses a thermal limit of 75 degrees centigrade (50 degrees centigrade rise above an ambient of 25 degrees centigrade with 1.4 mile-per-hour wind) which is based upon 75 per cent of the maximum current carrying capacity of the conductor. The new *AHT* (Anaconda Hy-Therm) copper is claimed to operate comparably at 115 degrees centigrade; however, 100 degrees centigrade is suggested as a conservative value for design.

If 100 degrees centigrade is used for this *AHT* copper, the authors point out that for 500,000-circular mil conductors the current rating could be increased from 835 to 995 amperes for a 19.6 per cent increase over commercial brand copper.

It would, perhaps, be undesirable, if this conductor were used, to increase the present current in the conductors of the Bonneville Power Administration system by 19.6 per cent because of the increase in the power losses. However, the use of *AHT* copper appears to provide a safety factor which could result in a considerable reduction in annealing effects during overload conditions.

Both system stability and power loss would limit the advantageous use of this conductor in the Bonneville Power Administration system, except in short heavily-loaded transmission lines.

Leonard M. Olmsted (Duquesne Light Company, Pittsburgh, Pa.): This paper is a most welcome addition to the technical information required for intelligent and safe loading of hard-drawn copper conductors. Now, for the first time, operating engineers are able to discard approximations derived from various and scattered sources and to make use of an authoritative and comprehensive survey of the effect of operating temperatures upon the tensile strength of hard-drawn copper conductors.

A group of papers published early in 1943 reported the efforts of several engineers to make higher ratings available for war-time use on overhead circuits. In our own case, the beginning was late in 1938, nearly 12 years ago, when we were contemplating an increase in peak from 367 megawatts to a maximum of approximately 460 megawatts. With only slight changes, other than adding generating capacity, this bulk power system has since carried 719 megawatts.

Under such circumstances, it is quite natural that each important addition to the technical literature has been reviewed carefully to determine whether the original premises were sound, and to improve upon the accuracy of our ratings. The effect of several such reviews is shown in Figure 1 of the discussion. These time-temperature curves are plotted, not for an arbitrary five per cent loss of strength, but for what was considered to be the limit before replacement would be necessary. The curve entitled "March 1943—51.6 per cent anneal" reproduces the data used in our earlier technical paper. Additional data secured from discussion of this paper justified revision to the curve entitled "June 1943—51.6 per cent anneal." Tests of elastic limit after partial annealing during 1944 forced us to revise the time-temperature limit to the curve entitled "December 1944—39.6 per cent anneal," which was used for some time as the basis for our overhead line ratings.

Subsequent to the termination of hostilities, our thinking relative to ratings has become somewhat more conservative, particularly reflected in the additional restriction that the factor of safety should be maintained above 1.66 in order to comply with the general requirements of the National Electric Safety Code. The data presented in this paper have been plotted accordingly as shown by the dash line entitled "1948—34.2 per cent anneal." Inasmuch as the paper also shows an accelerated loss of strength under tension, a further reduction has been estimated in deriving the final curve entitled "1948—34.2 per cent anneal and tension." In my opinion, there is surprisingly close agreement between curves derived from these two radically different sources, the principle difference being in the slope of the curves. The time-temperature limits deduced from the original 1943 curve and from the final 1948 curve are shown by the circles "C 1" representing 1943 continuous, "LF 1" 1943 load factor, "LF 4" 1948 load factor, "E 1" 1943 emergency, and "E 4" 1948 emergency after "S 4" switching period. The change in these time-temperature limits is well within the 20 per cent margin recommended to cover suspected inaccuracies in the 1943 data, and the final ratings are almost identical.

Figure 2. Wind velocities recorded at various air temperatures

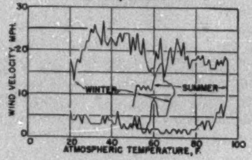

Figure 3. Wind velocities recorded at various effective air temperatures including sub heating

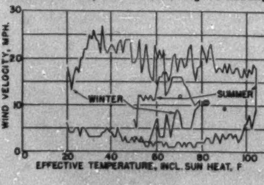

Figure 4. Conductor temperature range of number 4/0 7-strand bare copper at 510 amperes

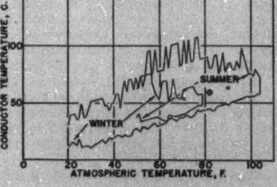

The authors' discussion of the effects of chemical composition, tension loading, intermittent heating, and manufacturing technique helps greatly to settle the questions which have persisted about these aspects of the thermal capability of copper conductors. Their treatment of current ratings, however, could prove somewhat misleading. After showing that a maximum temperature of 75 degrees centigrade on hard-drawn average copper causes a five per cent loss of strength in 7,000 hours, they then propose to rate the conductors for that temperature with 25 degrees centigrade ambient air moving at 1.36 miles per hour crosswise to the conductor, giving a rating of 480 amperes continuous for number 4/0 stranded copper. While the probable distribution of coincident velocities and air temperatures in this latitude is such that the temperature of the conductor would seldom exceed 75 degrees centigrade, and much of the time would be materially lower, short-time emergency ratings appreciably higher than 480 amperes are necessary to make firm this continuous rating.

Data from a recent analysis of 4/0 conductor loading at 510 amperes illustrate this point. Figure 2 of the discussion shows the range of coincident wind velocities and ambient temperatures from approximately 10,000 hourly observations. Figure 3 of the discussion shows the same data with the temperature adjusted during sunshine hours for sun heating, indicated as "effective temperature." Here the concentric circle denotes the annual equivalent effective temperature and wind velocity, and the single circles show the summer and winter allocations of it. Applying these cooling limitations to a 4/0 conductor carrying 510 amperes continuously gives the conductor temperature pattern shown in Figure 4 of the discussion. A practical emergency short-time rating to use with a 510-ampere normal rating would be 760 amperes; the conductor temperature pattern for this current is shown in Figure 5 of the discussion. The temperature reaches such a high level that there seems to be no practical way to maintain safe clearance over ground and structures underneath the spans, and there is considerable doubt that permanent splices and joints could be made.

This recent analysis was made primarily to check the validity of our earlier estimate that a 20-year life represented an economic balance of carrying costs, maintenance costs and line losses. It was found that a life span on the order of 75 years gives a lower annual cost per ampere without serious

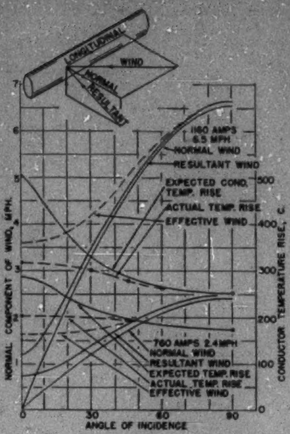

Figure 6. Effect of wind angle upon conductor cooling

sacrifice of ratings. These ratings, incidentally, are 420 amperes normal at system load factor, and 580 amperes for an emergency day following a 1-hour switching period at 630 amperes. The maximum conductor temperature is 125 degrees centigrade, which is about the highest value for which we believe it is feasible to provide and maintain satisfactory clearances to ground and structures beneath the line.

Calculations of the dissipation of heat from conductors must assume some definite angle of incidence of the moving air against the conductor. Common practice is to reduce the wind velocity by some arbitrary factor and assume the angle to be 90 degrees. Figure 6 of the discussion is presented to show the importance of this angle of incidence. Theoretically wind in a longitudinal direction has no normal component, consequently its cooling effect upon the conductor should be similar to still air, and the only normal component of wind would be in a vertical direction caused by heating of the air surrounding the conductor. For other angles between 0 and 90 degrees, the resultant of this vertical movement and the normal horizontal movement is plotted together with the expected conductor temperature rise, for two different conductor currents and wind velocities. Plotting on this same diagram the limited experimental data, shown by circles, implies that the actual temperature is not nearly as severe as calculations indicate. Inasmuch as the cooling effect of a minimum wind at zero angle establishes the maximum conductor temperature for which clearance must be provided, sometimes at considerable cost, this problem appears to justify further investigation.

After such a discussion, you may well wonder what value can be attached to the development of Hy-Therm copper for conductors. Economic considerations are such that utilization of the greater available normal capability does not appear attractive, but there is no question that a considerable factor of safety has been added. The restriction of emergency ratings for present copper solely to conditions arising from accidental loss of capacity certainly could be liberalized, particularly to facilitate maintenance work. It must be assumed, of course, that these improved thermal characteristics have been attained without sacrificing any qualities which are important in overhead conductors.

In closing this discussion, I wish once more to compliment the authors for their valuable contribution to the literature on copper conductors and to state the opinion that it, together with concurrent developments in related materials, will enable utility operating engineers to establish safer and more satisfactory ratings for their overhead plant.

K. S. Wyatt (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): This paper on the uses of coppers with higher annealing points for over-head conductors to permit higher normal and emergency current loading is very interesting. The authors are to be congratulated.

They have raised the annealing point without appreciable change in electrical conductivity by adding trace elements to a pure grade of electrolytic copper. In Table II they list 12 such elements. It should be pointed out that it is important to control the quantities of certain of these trace elements within narrow limits, otherwise the development loses its significance.

Of course, the pronounced effect of trace elements on the properties of copper is not entirely unknown, in fact considerable work has been done in this field, as is evidenced by the list of references in the authors' paper. The use of these trace elements commercially is, however, a relatively new and important departure.

It must not be thought that there is one, and only one, combination of these trace elements which yields a copper with a high anneal point. Our own metallurgical department has had considerable experience in this field. They report that they have developed a high anneal point copper having similar properties to the copper described by the authors, and are currently supplying the requirements of utility engineers for this type of conductor.

L. F. Hickernell, A. A. Jones, and C. J. Snyder: In general, the comments by the discussors appear to center more on the bases chosen for comparison, rather than on the experimental data presented in the paper. In this connection, it was not our intention to establish absolute methods (as for current-carrying-capacity calculations) or bases (such as ambient temperature, permissible loss in strength, wind velocity, and so forth) for making the comparisons, but instead to use those accepted most generally in the literature so that some approximate evaluation could be made of the new material.

It appears that Olmsted is in general agreement with our approach to the annealing problem and that he does not question the data presented. Some leeway must be allowed and judgment exercised in the choice of a suitable limiting parameter of loss in strength. Strictly for purposes of comparison, we chose the 5 per cent reduction because it is conservative and has been used previously (see reference 20 of the paper). Similar comparisons could be made on the basis of elastic limit after annealing (but there is a scarcity of authoritative data on this characteristic) or final factor of safety (ratio of partially annealed strength to design tension). The general results of such comparisons would be similar.

The discussion of current ratings also was included only for purposes of comparison. For this reason, only a relatively few ratings were given, sufficient only to establish that the allowable increase is in the order of 20 per cent. The choice of 75 degrees centigrade operating, 25 degrees centigrade ambient temperature and 2 feet-per-second crosswise wind was based on rather widespread usage of these conditions for tabular ratings (see reference 11 of the paper) with no indication that they have not proved satisfactory in service. Basic data on long-time annealing characteristics of commercial coppers were presented in such form that the user could apply them to determine current ratings under any particular set of local weather conditions in which he was interested. This applied equally to continuous ratings and emergency ratings.

We believe the possible increase in sag and decrease in line clearance due to higher operating temperatures has been overestimated. For example, with a number 4/0 American wire gauge 7-wire hard-drawn copper conductor on a 500-foot span, the increase in sag due to an increase in operating temperature from 75 to 100 degrees centigrade is only 1.3 feet. National Electrical Safety Code clearances are set at 60 degrees Fahrenheit and presumably they are sufficiently conservative to provide adequate clearance at any operating temperatures under all normal conditions of line installation. The slight increase in sag due to higher conductor temperatures shown before indicates this to be so. Similarly, if the span length is adjusted to maintain the same sag, only a slightly larger number of supports is required. For example, using the same conductor cited before, the sag in a 478-foot span at 100 degrees centigrade is the same as that in a 500-foot span at 75 degrees centigrade and the corresponding numbers of structures per mile are 11.1 and 10.6, an effective increase of one structure in two miles of line.

There are so many varieties of connectors used in line construction that no general statement regarding their thermal capacity is possible. However, tests on splicing and dead-end connectors of the type which we make, have shown that they run considerably cooler than the conductor to which they are attached (see reference 13 of the paper). Therefore permanent splices could be made for operation at the higher temperatures.

The discussion of angle of incidence of wind to the conductor appears to be correct theoretically but is difficult to apply practically because of the many variables involved.

Changes in line direction and in contour, sag in the conductor, and continual variation in wind direction all contribute to producing a higher component of wind normal to the conductor. As a matter of fact, Olmsted's data show this to be true, because "actual" temperature rises plotted in his Figure 6 show little variation with angle of incidence.

The improved thermal characteristics of Hy-Therm copper have been obtained without sacrificing any qualities which are important in overhead conductors. Hy-Therm is a commercial copper, developed to have the outstanding property of resistance to annealing. Its purity, electrical conductivity, strength, elongation, fatigue resistance, and crystal structure are all similar to regular copper wire. It meets all existing industry specification requirements for electrolytic copper wire and cable.

Referring to the discussion by the engineers of the Bonneville Power Administration: we appreciate that there are factors other than annealing (such as system stability and power loss) involved in selecting ratings of transmission conductors under normal operating conditions. In many cases, these other factors will govern in establishing normal operating ratings. However, the additional resistance to annealing inherent in Hy-Therm copper is of real value in permitting higher emergency loadings, as for example in the case of failure in one circuit of a double-circuit line and the remaining circuit has to carry practically double load for some time.

Answering Wyatt's discussion, the chemical analysis given in Table II of the paper is a composite list of the 12-trace elements which occurred in a total of 21 brands of copper.

Not all these elements occur in any one brand. Furthermore, only a few of them have any appreciable effect on the annealing characteristic. In Hy-Therm copper the complexity of control is avoided by using a very pure electrolytic copper to which small quantities of simple hardening agents are added.

It was not our intent in the paper to imply that only one combination of elements could accomplish the result desired. It is recognized that the annealing resistance of other brands of copper could be increased by suitable adjustment of their chemical composition. If this has been done commercially, published data similar to that given for Hy-Therm would be of interest to the industry.

Universal Curves for D-C Controllable Reactors

Synopsis: This paper describes a graphical method for calculating the steady-state characteristics of d-c controllable reactors, using universal curves drawn on a per-unit basis. The phenomenon of d-c flux reduction, caused by the alternating current acting on the nonlinear flux path, is pointed out, and certain general conclusions are drawn. Comparison with experimental results indicates that the accuracy is reasonably good.

A D-C controllable reactor is an iron-cored inductor in which the a-c impedance can be varied over wide limits by magnetically saturating the iron with an auxiliary d-c winding. Because of its ruggedness, ease of control, and low losses, it has found ever wider application as a control device.

Many of the applications and general characteristics of the d-c controllable reactor have already been described in the literature,[1-10] but no reasonably complete quantitative theory of its operation has hitherto been published. The widespread use of these devices has made it seem desirable to investigate their properties analytically. The purpose of this paper is to present in an easily usable form the method and results of such an analysis. The present paper treats the steady-state characteristics only. The results are applicable to the calculation of the characteristic curves of a reactor from either its d-c or its a-c saturation curve. The computation can be made on either an rms or an average current basis. The universal curves presented herein can be used in a straightforward quantitative fashion, or they can be used in a qualitative or semiquantitative fashion, to enable one to determine, for example, the effect of using a magnetic material with different characteristics. The analysis also enables one to calculate the d-c flux linkage, a quantity which is difficult to measure in the d-c controlled reactor and which, as will be shown, is only partially determined by the control current. A knowledge of the d-c flux linkage is, of course, essential to the computation of transient characteristics.

The method of calculation has been checked experimentally for a number of 60-cycle reactors with silicon steel cores and for two 400-cycle reactors with high-permeability cores. The error in the computed rms alternating current has been generally less than ten per cent for silicon-steel reactors. The error in the average alternating current is generally smaller than that of the rms current. A somewhat greater error is obtained with high-permeability cores, ranging sometimes up to 15 per cent on the conservative side. These errors are within the expected limits for calculations on nonlinear circuits.

Description of Operation

A highly important phenomenon in the operation of the d-c controlled reactor is the reduction in d-c flux caused by the alternating current acting on the nonlinear flux path. Consequently, a brief description of the operation of the reactor will be given with the view of showing how this phenomenon takes place.

Figure 1 shows schematically three familiar forms of the d-c controlled reactor. In each case, the two a-c windings can be connected either in parallel, as shown, or in series. The same theory applies to all three forms of the reactor and, for definiteness and convenience, we shall refer to that of Figure 1(c). This latter type is the only one in which the a-c and d-c flux paths are congruent. Therefore, for the other types, additional current for the extra d-c flux path must be added to the direct current as read from the universal curves.

A-C COILS IN PARALLEL

Referring to the reactor of Figure 1(c), and considering for the moment the condition of zero direct current, it can be seen that each half of the device behaves separately as an iron-cored reactor, with the coil current corresponding to the magnetizing current of a transformer. Since the a-c fluxes in the two halves are in opposite directions with respect to the d-c coil, very little a-c voltage is induced in the d-c winding.

Assume, for convenience, that the a-c and d-c turns are equal and that hysteresis is negligible. If direct current is applied to the d-c winding, a certain d-c flux will be set up in the path shown in Figure 1(f). The magnetization curve for the left half of the reactor is shown in Figure 2(a). The net flux linkages in this element consist of the d-c linkages, ψ_0, plus an a-c component which depends upon the applied voltage. The time variation of the flux in the left element is shown in Figure 2(a), assuming a sinusoidal voltage. The current wave shape can now be traced point by point from the magnetization curve, with the result shown in the lower right-hand quadrant of Figure 2(a), in which the time axis for the current runs vertically downward. Since no direct current will be present in the a-c coil winding in steady state, the average value must represent the current in the d-c winding. The variation about this average is the current in the a-c coil, and is redrawn in Figure 2(b).

Paper 49-4, recommended by the AIEE transformer committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted October 21, 1948; made available for printing November 24, 1948.

WALTER C. JOHNSON is professor of electrical engineering at Princeton University, Princeton, N. J.; B. C. MERRELL is an engineer at Procter and Gamble, Cincinnati, Ohio; and R. E. ALLEY, JR., is assistant professor of physics at the University of Richmond, Richmond, Va.

The work presented in this paper has been supported in part under a contract with the General Electric Company.

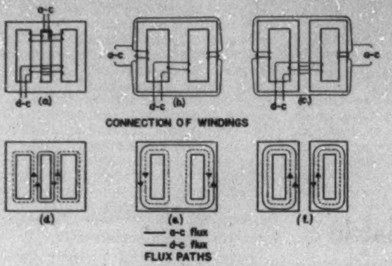

Figure 1 (left). Schematic diagrams of different types of d-c controllable reactors

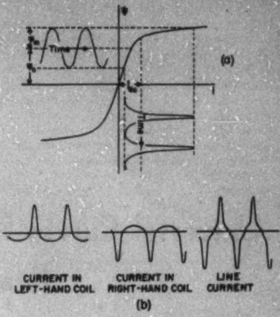

Figure 2 (right). Flux linkage and current relations

We now can observe the important point that, because of the nonlinearity of the magnetization curve, we must expect that the average flux and the average current will not intersect on the curve; in particular, ψ_0 will always be lower than the intersection of I_{dc} with the curve. Under the usual operating conditions, the effect is very much greater than can be shown in the illustration, a ratio of ten or more between I_{dc} and the intersection of ψ_0 being not at all unusual. The d-c flux and direct current will intersect on the magnetization curve only when the a-c voltage is extremely small. The reduction in ψ_0 with increasing a-c voltage can be regarded as caused by a demagnetizing action that the alternating current exerts on the d-c flux path because of the nonlinearity in the characteristics of the core material.

Considering next the right-hand half of the reactor, it can be seen from symmetry considerations that the alternating current will be similar to that in the left-hand half, but reversed and shifted in phase position by half a cycle. This is shown in Figure 2.

The alternating line current is the sum of the two coil currents, and, as shown in Figure 2, contains odd harmonics only. The even harmonics circulate between the two coils.

A-C Coils in Series

The foregoing discussion has assumed that the a-c coils are connected in parallel. With this arrangement, a sudden change in the control voltage will cause a transient current to circulate between the two a-c coils, temporarily bucking out the normal d-c flux and slowing down the response of the reactor. When a somewhat greater speed of response is desired, the two a-c coils may be connected in series, thus eliminating the path for the circulating transient. However, this does not permit the flow of even harmonics of current between the a-c coils, and, instead, even harmonics appear in the d-c winding. The ratio of d-c to a-c turns is often rather large, and if the source of direct current offers a high impedance to the flow of harmonic currents, the a-c voltage at the terminals of the d-c winding may become large. In the following discussion of the series connection, we shall assume that the d-c source has a low a-c impedance.

If the series-connected reactor of Figure 3 is controlled from a low-impedance d-c source, no appreciable a-c voltage can be developed across the d-c coil. Since the a-c and d-c coils on each core are closely coupled, this can be true only if the instantaneous voltages across the two a-c coils are at all times equal and in phase. Otherwise, transformer action would result in a net a-c voltage appearing across the d-c coil. If the applied voltage is sinusoidal, the voltage across each a-c coil will be a sine wave of half the line amplitude.

Assuming a unity turns ratio for simplicity, and designating the instantaneous magnetizing currents of the two halves by i_{m1} and i_{m2} respectively, we have, by reference to Figure 3

$$i_a+i_b=i_{m1} \tag{1}$$

and

$$i_a-i_b=i_{m2} \tag{2}$$

Adding and subtracting equations 1 and 2, we obtain for the instantaneous currents in the a-c and d-c windings respectively,

$$i_a=\frac{i_{m1}+i_{m2}}{2} \tag{3}$$

and

$$i_b=\frac{i_{m1}-i_{m2}}{2} \tag{4}$$

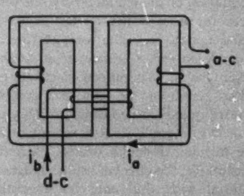
In contrast with this, we have for the parallel case $i_{\text{line}} = i_m + i_{m2}$ and $i_b =$ average value of i_{m1}.

If the line voltage considered in the discussion of the parallel case is doubled in magnitude and applied to the series-connected reactor, the voltage which the a-c coil of each half must absorb is the same as that causing the variation of flux linkages shown for the parallel case in Figure 2(a). The magnetizing currents will be the same as for the parallel case; therefore, referring to equation 3, the line current will be of the same form as previously but will have half the former magnitude. The current in the d-c winding will contain harmonics of even order (see Figure 4(b)), as can be shown from equation 4.

Method of Analysis and Assumptions

The mathematical analysis of circuits containing saturable iron depends primarily upon the use of an equation to represent the magnetization curve of the iron. Various methods have been suggested in the past, including the hyperbolic tangent, the power series, and a representation by the segments of straight lines. It has been recognized that the power series offers the possibility of considerable accuracy, but the objection has been that a series containing even a moderate number of terms is difficult to manipulate. The present analysis is based on the representation of the magnetization curve by an equation contain-

Figure 3. Series connection of a-c coils



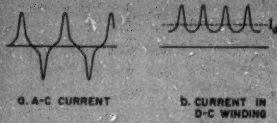


Figure 4. Currents with series connection; low a-c impedance in d-c supply

ing only one power term in combination with a linear term. The basic equation is

$$i = C_1\psi + C_n\psi^n \tag{5}$$

where

i = the instantaneous current,
ψ = the instantaneous flux linkage,
C_1, C_n, and n are constants which depend upon the shape of the magnetization curve.

The choice of this equation represents a compromise between the desire for accuracy and the need for simplicity in a difficult nonlinear problem. The equation lends itself to manipulation better than most, and experience with a number of different reactors has indicated that a wide variety of magnetization curves can be fitted with good accuracy. No provision has been made for the reverse curvature found at the lower end of the magnetization curve. For the present purpose, this was not of great importance, as it would affect the results mainly at the lowest a-c flux densities. A term representing hysteresis was originally added, but this was dropped because the additional complication did not seem to be justified.

In the analysis, the equations for the d-c magnetization curve and for the a-c saturation curve are related to each other. Calculations are then made for the unsymmetrically magnetized condition and the results are presented in the form of universal curves plotted in terms of dimensionless groups for n = 5, 9, and 15. Other values of n can be used by interpolation.

In addition to the assumptions mentioned in the foregoing paragraphs, the following assumptions were made so as to simplify the analysis without unduly affecting the accuracy.

1. The analysis is based upon a sinusoidal variation of flux with time. When the d-c excitation of the reactor is small, the impedance will be large, and most of the supply voltage will appear across the reactor. Under these conditions the flux will be nearly sinusoidal. Increased d-c excitation will reduce the impedance of the reactor; consequently, the current will increase and the reactor voltage will decrease. Under these conditions the terminal voltage and hence the flux may not be sinusoidal. However, it has been shown previously[11] that under low-voltage high-current conditions the characteristic curves of the reactor are little affected by the form of the voltage. Hence, in the working range of the reactor, reasonably accurate results can be obtained from computations made on the basis of a sinusoidal flux.

2. It is assumed that the flux follows the normal magnetization curve when the core is magnetized unsymmetrically. Experiments made on the usual types of transformer steel[13] have shown that this assumption should produce but little error except at low a-c flux densities. At low densities, the actual unsymmetrical hysteresis loop may be considerably inclined from the angle of the normal magnetization curve, and it is to be expected that the actual impedance will be lower than calculated. The error is in such a direction as to make the design more conservative.

3. The analysis assumes either that the a-c coils are connected in parallel or, if they are connected in series, that the source of direct current has a low a-c impedance.

4. Leakage flux is neglected.

The Universal Curves and Their Use

Preliminary Procedure

The universal curves are designed to be used in connection with the a-c saturation curve of the reactor as measured from the terminals of the a-c winding. As will be shown later, however, one can also work from the normal magnetization curve of the core material.

We shall assume that data are available on the relation between rms voltage and current as measured at the a-c terminals with zero direct current. The straight-line portion of the saturation curve (analogous to the air-gap line in machinery calculations) is first removed by subtracting the currents corresponding to this straight line. The saturation curve with the straight-line portion removed will be called the "reduced saturation curve." A base current, I_b, is then selected. The exact magnitude of this is not important, but it should be at least as large as the greatest expected alternating current in the reactor. The a-c voltage corresponding to I_b on the reduced saturation curve will be called the base voltage, E_b.

Since we are attempting to fit a power function, it might seem logical to plot the reduced saturation curve on log-log paper and measure the slope to the best straight line. However, this procedure is likely to overemphasize the lower portion of the curve and underemphasize the important top portion. Better results have been obtained by plotting the reduced saturation curve on the chart of Figure 5 and comparing with the power curves given. A per-unit basis is used in this chart, that is, one plots E/E_b and I/I_b. Interpolation can be used to find powers between the three shown. Reactors with silicon-steel cores have been found to fit a power curve remarkably well, as is illustrated in Figure 5 for a commercial reactor. The saturation curves of high-permeability cores do not fit as well, but the accuracy is still within reasonable limits.

The Universal Curves

Once the appropriate power has been determined for the reduced saturation curve, the universal curves of Figures 6 to 12 can be used directly to relate the a-c voltage and current, the required direct current, and the d-c flux of the reactor

Figure 5. Chart for fitting a power to a saturation curve

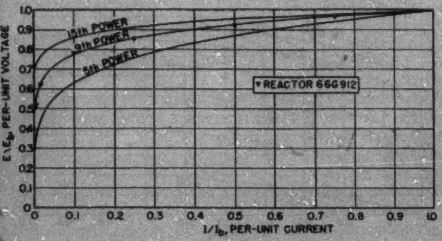

Figure 6. Universal curves for a fifth-power saturation curve, plotted in terms of effective current

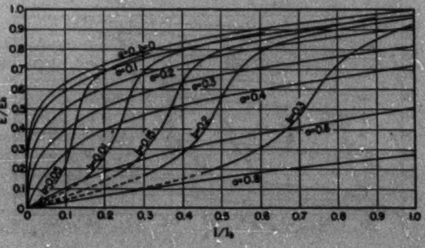

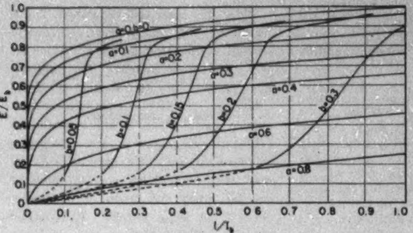

Figure 7. Universal curves for a ninth-power saturation curve, plotted in terms of effective current

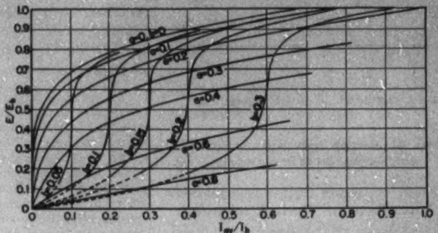

Figure 9. Universal curves for a fifth-power saturation curve, plotted in terms of average current

when operating with d-c saturation. A correction, generally small, must be added to take account of the straight-line portion previously removed from the saturation curve. This correction can be made graphically and is described later. Interpolation between the powers given can be made as necessary.

Figures 6 to 8 show, on a per-unit basis, the relations in terms of the rms current and voltage. Figures 9 to 11 show the corresponding relations for the average alternating current. In Figure 12 a comparison of the average currents obtained with curves of different powers is shown, together with the corresponding curves that would be obtained if the core material had ideal characteristics with a vertical side and a horizontal top. The small difference between the various average-current curves is striking.

The curves are plotted in terms of the following dimensionless groups:

E/E_b, where E is the rms voltage applied to the a-c terminals, and E_b is the rms base voltage selected previously.

I/I_b, where I is the rms alternating line current neglecting the straight-line correction, and I_b is the rms base current selected previously.

I_{av}/I_b, where I_{av} is the average alternating line current neglecting the straight-line correction.

$a=\psi_0/\psi_b$, where ψ_0 is the d-c flux linkage of one a-c coil, and ψ_b is the maximum a-c flux linkage which would be caused by the base voltage, E_b. ($\psi_b=\sqrt{2}E_b/\omega$).

$b=\dfrac{I_0}{I_b}\dfrac{N_{dc}}{N_{ac}}$, where I_0 is the current in the d-c winding, neglecting the straight-line correction. The quantity N_{dc} is the number of turns on the d-c winding; N_{ac} is the number of turns on one a-c coil in the parallel case, and is the total number of turns on both a-c coils in the series case.

STRAIGHT-LINE CORRECTIONS

The straight-line portion of the saturation curve adds a correction to the alternating current at any given a-c voltage as follows: to the rms current, I, as obtained from the universal curves, add the current given by the straight-line portion of the saturation curve at the given voltage to obtain the total rms line current; for the average current, I_{av}, as obtained from the universal curves, add 0.9 of the straight-line portion of the saturation curve to obtain the total average line current.

The straight-line portion of the saturation curve also adds a correction to the direct current. From the universal curve, read $a = \psi_o/\psi_b$ and compute a fictitious voltage $E_o = aE_b$. (Physically, this represents the a-c voltage which would produce a peak a-c flux equal to the d-c flux). Read the current corresponding to E_o from the straight-line portion of the saturation curve (see I_o' in Figure 13), and add to the direct current the following amount

$$\text{Additional direct current} = 0.707 I_o' \frac{N_{ac}}{N_{dc}} \quad (6)$$

ADDITIONAL D-C FLUX PATHS

When the reactor has a portion of the d-c flux path which is not traversed by the a-c flux, as in the reactors of Figure 1a and b, the additional direct current required for the added path can be found approximately as follows:

Compute the fictitious voltage $E_0 = aE_b$. At the value of voltage given by E_0, go horizontally across to the point P shown in Figure 13, which is located so that $m = 0.65\ n$. This point can be located with sufficient accuracy by eye. Read the current I_0'', and add to the direct current the following amount:

$$\text{Additional direct current} = 0.707 I_0'' \frac{N_{ac}}{N_{dc}} \; \frac{\text{Length of additional d-c flux path}}{\text{Length of a-c flux path for one a-c coil}} \quad (7)$$

EXAMPLE

The calculation of one point for the General Electric reactor Number *66G912* will be given to illustrate the method. The reactor is of the type shown in Figure

Figure 8. Universal curves for a fifteenth-power saturation curve, plotted in terms of effective current

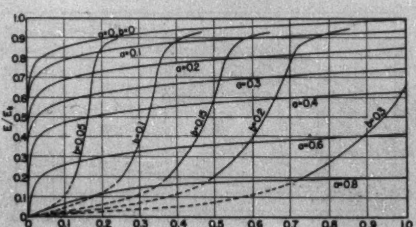

Figure 10. Universal curves for a ninth-power saturation curve, plotted in terms of average current

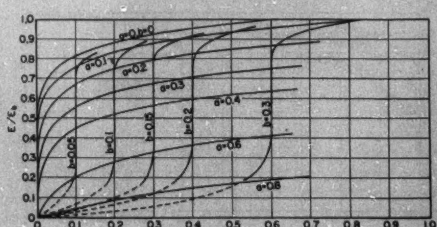

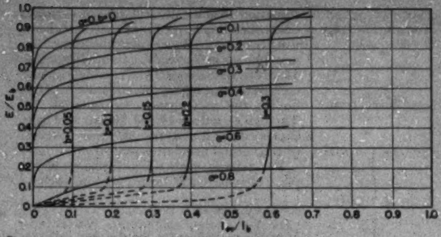

Figure 11. Universal curves for a fifteenth-power saturation curve, plotted in terms of average current

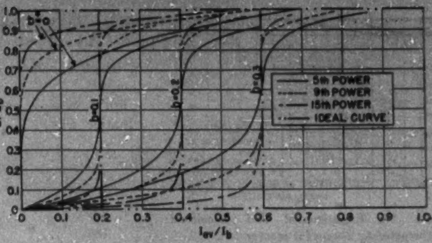

Figure 12. A comparison of the average-current curves

1(a), and, with the a-c windings connected in parallel, has the a-c saturation curve given by the top solid curve of Figure 14. Several points on this saturation curve have been plotted on the chart of Figure 5, using the base values $I_b=28$ amperes and $E_b=200$ volts. The curve is seen to fit a ninth-power equation quite well without removal of a straight-line portion. The reactor has $N_{ac}=230$ for one a-c coil and $N_{dc}=4{,}000$.

We shall calculate the direct current necessary to produce an alternating current of 20.9 rms amperes at 140 rms volts. Using the ninth-power chart, Figure 7, with $E/E_b=140/200=0.7$ per unit and $I/I_b=20.9/28=0.746$, we read from the chart $b=0.25$ and $a=0.32$. Then, from the definition of b, we have

$$I_o=b\,I_b\frac{N_{ac}}{N_{dc}}$$

$$=0.25\times 28\times\frac{230}{4000}=0.403 \text{ ampere}$$

Since no straight-line portion was removed from the saturation curve, the only other calculation necessary is the direct current required for the additional d-c flux path in the outer legs. The ratio of this length to the length of the a-c flux path for one a-c coil is measured to be 0.60. We compute the fictitious voltage $E_o=aE_b=0.32\times 200=64$ volts, and, following the method shown in Figure 13, we use Figure 14 and find I_o'' to be 0.3 ampere. Then, from equation 7, we have

$$\text{Additional direct current}=0.707\times 0.3\times\frac{230}{4000}\times 0.60=0.007 \text{ ampere}$$

The total required direct current for $E=140$ volts, $I=20.9$ amperes, is therefore

$$I_{dc}=0.403+0.007=0.410 \text{ ampere}$$

The measured value at this point was 0.416 ampere.

A complete set of calculated points for both rms and average currents is shown in Figure 14, together with the characteristic curves obtained experimentally.

Discussion of the Results

In the section entitled Description of Operation, the demagnetizing action of the alternating current upon the d-c flux was mentioned. This phenomenon is shown quantitatively in all of the universal curves, for, if one follows a curve of constant per-unit direct current, b, in the direction of increasing alternating current, the value of d-c flux linkage decreases markedly, as indicated by a reduction in the quantity $a=\psi_o/\psi_b$.

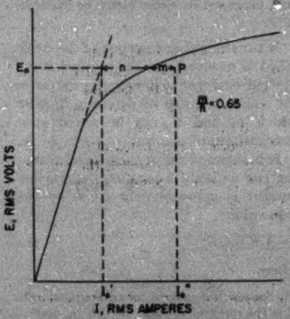
An interesting comparison is obtained between the values of direct current required for core materials with different saturation characteristics. Considering first Figures 6 to 8 for the rms current, it can be seen that the fifth-power curve for a per-unit direct current of 0.2 corresponds roughly with the fifteenth-power curve for $b=0.15$. The reduction in d-c excitation afforded by the much sharper-breaking curve is appreciable but perhaps not as great as one might expect. The reason is that the phenomenon of d-c demagnetization is stronger for the faster-breaking curves and tends to reduce their effectiveness. Figure 12 shows a similar comparison on an average alternating current basis, and here the difference between the various powers is strikingly small. In the lower-voltage region the sharper-breaking curves have an appreciable advantage, but at the higher voltages the reverse is actually true. Even the ideal magnetization characteristic with a vertical side and horizontal top does not affect the results greatly. For this latter case, the average-current characteristic curves have vertical sides at $I_{av}/I_b=2b$, that is, at $N_{ac}I_{av}=2N_{dc}I_o$, as has been shown previously by Uno Lamm.[1] The average-current curves are, of course, the important ones in circuits where the output is rectified, including those in which rectified feedback is employed.

The order of magnitude of the straight-line corrections is interesting. The correction is most important when the value of a is large, that is, at the lower voltages. In the region of low a-c voltage and current, the percentage increase in direct current due to the straight-line correction may be considerable in some cases. At the higher a-c voltages it is often negligible.

In the universal curves of Figure 6 to 11 it will be seen that the characteristics at low a-c voltages are shown dotted. In this region one should deal with the incremental permeability, and, since the present analysis assumes that the flux follows the normal magnetization curve, the figures do not give reliable information at low voltages. In general, the a-c impedance in the very-low-voltage region will be somewhat smaller than the figures indicate.

An aspect of the calculations which has not been emphasized is the fact that the charts make it possible to calculate the

Figure 13. Graphical method for computing the additional direct current required for an added d-c flux path



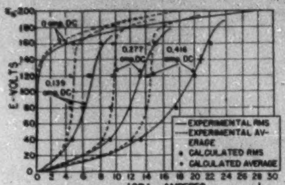


Figure 14. Experimental and calculated characteristic curves for reactor *66G912*

d-c flux in the reactor without difficulty. This quantity is of major importance in the transient operation of the reactor. It can not be measured easily under operating conditions because of the slowness of response of the reactor, and, as has been mentioned previously, it is not simply related to the direct control current. Work has been started on an investigation of the transient response of reactors, using the computed values of d-c flux as a basis for calculation. The preliminary results have been encouraging, and we hope to report on this work later.

Relation between Normal Magnetization Curve and A-C Saturation Curve

In some cases, it may be found desirable to make calculations from the normal magnetization curve of the core material rather than from the a-c saturation curve. The analysis shows that the following relations hold with good accuracy.

We first assume that the normal magnetization curve can be represented by the expression

$$i=C_1\psi+C_n\psi^n \qquad (8)$$

where

i is the instantaneous current in one a-c coil
ψ is the instantaneous flux linkage of that coil, expressed in weber-turns, or maxwell-turns$\times 10^{-8}$.

If the straight-line portion of the curve $(C_1\psi)$ is removed and the reduced curve plotted on a per-unit basis on Figure 5, the value of n can be determined, after which C_n and C_1 can be found in a straightforward manner.

It is shown in the analysis that, assuming two a-c coils in parallel, the rms line current is approximately given by the expression

$$I=A_1E+A_nE^n \qquad (9)$$

where

I is the rms line current for two parallel coils
E is the rms coil voltage $A_1=2C_1/\omega$, and

$$A_n=2\sqrt{\frac{\Gamma(n+1/2)}{\sqrt{\pi}\,\Gamma(n+1)}}\left(\frac{\sqrt{2}}{\omega}\right)C_n \qquad (10)$$

in which Γ indicates the gamma function.[13,14]

For n = 5, 9, and 15, we have from equation 10

$$\left.\begin{aligned}A_5&=\frac{5.61}{\omega^5}C_5\\A_9&=\frac{19.5}{\omega^9}C_9\\A_{15}&=\frac{138}{\omega^{15}}C_{15}\end{aligned}\right\} \qquad (11)$$

For two series-connected a-c coils, the foregoing values of A should be divided by 2, and E represents half the line voltage.

The foregoing relations make it possible to predict the wave shape of the magnetizing current from a knowledge of the shape of the a-c saturation curve. An in-phase current representing iron losses should be added to the current computed from equation 8 when necessary. The results of such a calculation are shown in Figure 15 for the reactor used in the previous example. The crosses mark calculated points and the solid curve shows a half cycle of the actual wave shape as obtained from an oscillogram. The agreement is seen to be quite good.

Appendix I. Analysis

Rms Current

Consider the equation which expresses the instantaneous current in one a-c coil in terms of the flux linkages

$$i=C_1\psi+C_n\psi^n \qquad (12)$$

If the alternating voltage is sinusoidal and there is no d-c saturation, the flux linkages can be expressed as

$$\psi=\psi_m\sin\omega t \qquad (13)$$

where

$$\psi_m=\frac{\sqrt{2}E}{\omega}\text{ weber turns} \qquad (14)$$

and E is the rms coil voltage.

Substituting equation 13 into 12, squaring, and integrating, we obtain for the mean squared coil current

$$I_c^2=\frac{C_1^2\psi_m^2}{2}+\frac{2C_1C_n\Gamma[(n+2)/2]}{\sqrt{\pi}\,\Gamma[(n+3)/2]}\psi_m^{n+1}+\frac{C_n^2\Gamma(n+1/2)}{\sqrt{\pi}\,\Gamma(n+1)}\psi_m^{2n} \qquad (15)$$

For values of n that are not too large, equation 15 is nearly a perfect square, and its approximate square root is

$$I_c\approx\frac{C_1}{\sqrt{2}}\psi_m+\sqrt{\frac{\Gamma(n+1/2)}{\sqrt{\pi}\,\Gamma(n+1)}}\,C_n\psi_m^n \qquad (16)$$

Equation 16 generally will give good results even when n is large, for the second term is usually the major one, and the error that arises in the cross-product term of equation 15 is then not serious. For two identical a-c coils connected in parallel, the line current is double the value given by equation 16. Through equations 14 and 16, we now have expressed the a-c saturation curve in terms of the normal magnetization curve.

When d-c saturation is present, we use in place of equation 13 the expression

$$\psi=\psi_0+\psi_m\sin\omega t \qquad (17)$$

in which ψ_0 represents the d-c flux linkage. Substituting equation 17 into equation 12, expanding the quantity ψ^n by the binomial theorem, and then expanding the powers of the sine function into harmonics, we obtain a Fourier series for the required magnetizing current. This series contains (1), a constant term which represents the required direct current, (2), even harmonics, which circulate between the two a-c windings in the parallel case and flow in the d-c winding in the series case, and (3), odd harmonics, which constitute the alternating line current. For example, the d-c term for $n=5$ is

$$I_{dc}=C_1\psi_0+C_5\psi_0(\psi_0^4+5\psi_0^2\psi_m^2+1.87\psi_m^4) \qquad (18)$$

and, for two a-c coils in parallel, the magnitude of the fundamental component of the line current is

$$I_1=2C_1\psi_m+10C_5\psi_m(\psi_0^4+1.5\psi_0^2\psi_m^2+0.125\psi_m^4) \qquad (19)$$

The influence of the a-c flux on the required direct current for a given value of ψ_0 is seen clearly in equation 18.

The expressions for the amplitudes of the various odd harmonics are squared and added, the results being nearly a perfect square. The approximate square root yields an expression for the rms value of the line current. For example, for $n=5$ and $\psi_0/\psi_m=0.5$, we obtain

$$I_{rms}\approx\sqrt{2}C_1\psi_m+4.20C_5\psi_m^5 \qquad (20)$$

Similarly, from equation 18, we have for $\psi_0/\psi_m=0.5$

$$I_{dc}=C_1\psi_0+1.59C_5\psi_m^5 \qquad (21)$$

Now, we subtract the straight-line portions of both expressions, then express ψ_m in terms of E by means of equation 14, and finally divide both sides by the base current $I_b=5.61C_5(E_b/\omega)^5$. Thus, we obtain the following expressions for the alternating and direct currents with the straight-line portions removed (the turns ratio will now be taken into account for the direct current)

$$I/I_b=4.24(E/E_b)^5 \qquad (22)$$

and

$$I_0N_{dc}/I_bN_{ac}=1.60(E/E_b)^5 \qquad (23)$$

By means of these relations, various points can be found along a curve corresponding to $n=5$ and $\psi_0/\psi_m=0.5$.

Similar computations will yield curves for other values of ψ_0/ψ_m and n. In plotting the charts, the parameter $a=\psi_0/\psi_b=(\psi_0/\psi_m)(E/E_b)$ was used instead of ψ_0/ψ_m, as the former is more convenient in practical calculations.

Average Current

For the condition of no d-c saturation, we substitute equation 13 into 12 and integrate to find the average current over one-half cycle. This yields the following result

$$I_{av} = \frac{2}{\pi} C_1\psi_m + \frac{\Gamma[(n+1)/2]}{\sqrt{\pi}\Gamma[n/2+1]} C_n\psi_m^n \text{ amps per coil} \quad (24)$$

For two identical a-c coils connected in parallel, the average line current is double the foregoing value.

When d-c saturation is present, we return to the previous analysis used for the rms case and integrate the current composed of all the odd harmonics. For example, for $n=5$ and $\psi_0/\psi_m=0.5$, we obtain for the average line current

$$I_{av} = \frac{4}{\pi} C_1\psi_m + 3.22 C_5\psi_m^5 \quad (25)$$

If we now subtract the straight-line portion of this expression, then express ψ_m as $\sqrt{2}E/\omega$, and finally divide both sides of the equation by the base current $I_b = 5.61 C_5(E_b/\omega)^5$, we obtain the relation

$$\text{Reduced } I_{av}/I_b = 3.25(E/E_b)^5 \quad (26)$$

By means of equations 23 and 26, points can be found along a curve corresponding to $n = 5$ and $\psi_0/\psi_m = 0.5$. Similar calculations will yield the curves for other values of ψ_0/ψ_m and n.

Appendix II. Direct Current Required for Additional D-C Flux Path

In this section, we shall derive an approximate graphical method for computing the additional direct current required for the portion of the d-c flux path that is not traversed by the a-c flux. If we assume that this additional path has the same magnetic characteristics as the main flux path, the equation $i = C_1\psi + C_n\psi^n$ will apply, provided that the coefficients are altered to take into account the turns ratio and the different length involved. Therefore, the additional exciting current is given by the expression

$$I_0' = \frac{N_{ac}}{N_{dc}} \frac{\text{length of additional d-c flux path}}{\text{length of flux path for one a-c coil}} \times (C_1\psi_0 + C_n\psi_0^n) \quad (27)$$

Now, we know that

$$\psi_0 = a\psi_b = \frac{\sqrt{2}aE_b}{\omega} \quad (28)$$

Hence, substituting equation 28 into 27 and using equation 10 to eliminate C_1 and C_n in favor of A_1 and A_n, we obtain

$$I_0' = \frac{N_{ac}}{N_{dc}} \times (\text{ratio of lengths}) \times \left[\frac{A_1}{\sqrt{2}}(aE_b) + \frac{A_n}{\sqrt[n]{\frac{\Gamma(n+1/2)}{\sqrt{\pi}\Gamma(n+1)}}}(aE_b)^n \right] \quad (29)$$

This can be rewritten as follows, using E_0 to denote the product aE_b

$$I_0' = \frac{N_{ac}}{N_{dc}} \times \text{ratio of lengths} \times \frac{1}{\sqrt{2}}(A_1E_0 + kA_nE_0^n) \quad (30)$$

where

$$k = \frac{1}{\sqrt{2}\sqrt[n]{\frac{\Gamma(n+1/2)}{\sqrt{\pi}\Gamma(n+1)}}} \quad (31)$$

The value of k does not vary rapidly with n and a mean value will be chosen for the range of interest. For $n=5$, 9, and 15, we compute from equation 31 that $k=1.44$, 1.64, and 1.86, respectively. If we choose a mean value of 1.65, the additional direct current can be read off the rms saturation curve at the voltage $E_0 = aE_b$ by increasing the contribution of the n-th power term by 65 per cent. This method is illustrated in Figure 13. The correction is, in general, only a small part of the total direct current, and the error made in supposing that k is always 1.65 is of little consequence.

Discussion

H. F. Storm (General Electric Company, Schenectady, N. Y.): This discussion intends to elaborate on one of the many interesting problems which are effectively described and clearly analyzed in this important paper, namely the phenomenon of d-c flux depression in the presence of an a-c flux. Without repeating the explanation, it is the object of this discussion to relate certain manifestations of this phenomenon which, without further knowledge, are quite puzzling.

Consider the two iron-core transformers which, as shown in Figure 1 of the discussion, are connected to form a saturable reactor. For a given control voltage E_d, a control current i_d will flow through the control windings W_2, the magnitude of this current being indicated by the d-c ammeter. The load consists of a resistance, for instance incandescent lamps. Suppose now that the load current is increased by connecting additional lamps into the circuit. As a result, the ammeter will indicate the intriguing fact that the control current i_d will also increase, though transiently, and then return slowly to its previous magnitude. For a decrease of load current, the control current

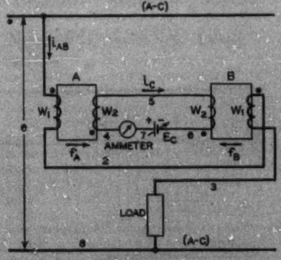

Figure 1 (right). Circuit diagram

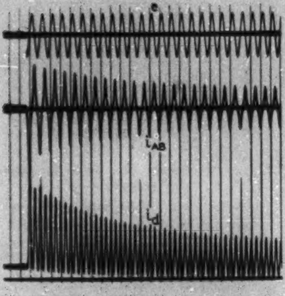

Figure 2. A-c voltage "e" suddenly applied near crest value

will transiently decrease and then build up to its previous value. Similar effects are obtained if the a-c voltage changes, no matter whether the load resistance is finite or zero.

One may be inclined to attribute these transient currents to the induction of electromotive forces from the W_1 windings into the W_2 windings. This, however, is not true. If the impedance in the control winding is low, and the load resistance is zero, the line a-c voltage divides equally between the two W_1 windings of transformers A and B. The voltages induced in the W_2 control windings are equal (providing the turn ratios are the same) but are opposing each other, as shown by the polarity marks. As a result, no net voltage is induced in the control circuit and therefore no current can be caused by these voltages.

The explanation of the phenomenon lies in the fact that by increasing the a-c flux, the d-c flux becomes smaller. The control current i_d causes a positive magnetomotive force f_A in core A, and a negative magnetomotive force f_B in core B, as shown by the polarity marks and arrows in Figure 1 of the discussion. Consequently the d-c flux is considered positive in core A and negative in core B. If an a-c flux is now superimposed, the absolute magnitude of the d-c flux decreases as shown in the author's paper. A decrease in the absolute magnitude of the d-c flux in core A means a change in a negative direction, and a change in core B in a positive direction. Therefore, the resulting electromotive forces will be positive at terminal 5 with respect to terminal 4 on transformer A, and positive at terminal 6 with respect to 5 on transformer B. These two electromotive forces are connected in series and are the cause for the transient current in the control circuit.

Figure 3. A-c voltage "e" interrupted

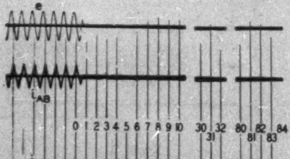

Figure 2 of the discussion shows an oscillogram of this phenomenon. First, without alternating current the control current i_d is seen as a constant quantity. Then when the alternating current has been connected to the circuit, at an instant corresponding to its crest value, the control current i_d is seen to surge up rapidly, thus causing a sharp increase of its average value; the ripple in the control current is caused by even harmonics, which are also present during steady-state operation. The average value of control current gradually subsides and reaches asymptotically the original value of i_d (this last phase is not shown in the oscillogram). It will also be observed that the load current i_{AB} is very large at the beginning of the transient and gradually declines to its steady-state value. This proves that the impedance of a saturable reactor changes transiently with a variation of load or a variation in supply voltage.

Figure 3 of the discussion shows a case where the a-c voltage was suddenly removed. The average value of the control current i_d drops very sharply upon the removal of the a-c voltage and then gradually increases to its original value.

E. C. Wentz and T. R. Specht (Westinghouse Electric Corporation, Sharon, Pa.): This paper should take its place as one of the important contributions to the basic theory of the d-c controllable reactor, and is the first, as far as I know, to relate basic simple data, such as the saturation curve, to the performance of the reactor.

The paper makes some assumptions which are admittedly not very close approximations to the facts. In discussing the paper, I believe we should examine some of the discrepancies with the idea of determining if further corrections can be made and if they are necessary for practical work.

The assumption that the saturation curve can be represented by the simple equation

$$= C_1\psi + C_n\psi^n$$

probably introduces relatively unimportant errors. In fact, many reasonably useful analyses has been done on the basis of the two-straight-line saturation curve, which is much less accurate.

The assumption that the flux is sinusoidal is approximate only for those applications where a sinusoidal voltage is maintained across the reactor. This is true for the current transductor, and for other current amplifiers where the impedance in series with the a-c winding is relatively small; consequently the application of this particular analysis is sharply limited. But the general method demonstrated in this paper can still be used for applications where the voltage is not sinusoidal, providing that it is some function which can be handled mathematically. Mathematical analysis will probably be more difficult for some of the other connections where the flux will not be sinusoidal, but the authors have shown a method of attack which is useful generally for other conditions besides that which they analyze.

The same comment applies to their assumption that the d-c circuit, or its equivalent, is able to carry or supply any amount of second harmonic current. This is frequently not true, but the analysis of the condition where it is true throws a great deal of light on the phenomena occurring when it is not true.

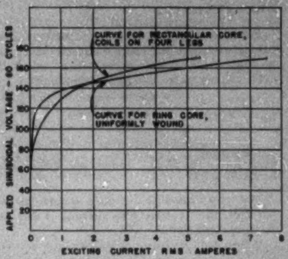

Figure 4. Saturation curves for two types of core—coil arrangement, using the same material

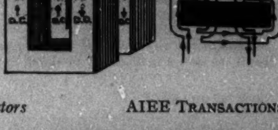
The most serious limitation of the method is its assumption that leakage flux can be neglected. Actually the authors do not quite mean what they say, because the saturation curve which they use has a great deal of leakage flux in it. That is, some of the flux which induces the voltages which are measured and plotted on the saturation curve is not confined entirely to the iron, but leaves the iron as soon as it can after going through the a-c coil and goes off into the air. When the iron is saturated, as it is in this type of reactor, the amount of flux which links the coil and then leaves the core is by no means negligible. This is shown in a semiquantitative way by Figure 4 of the discussion. The saturation curves in Figure 4 were made with two cores of the same cross-section and mean length of magnetic turn, but one was a ring core, with a winding uniformly distributed so that no flux would leave the core at any point, while the other was a rectangular core with coils on all four legs, a configuration which confines the flux to the core more effectively than if the coils were on only two legs of the core, but not as effectively as does the ring winding. The curve for the rectangular core shows that a very appreciable amount of this flux must be linking the turns in the coils without passing through much of the iron, because the curve rises considerably above the ring-core curve, and shows little sign of flattening off.

Another way of expressing the same thing is that it is necessary to consider the air-core inductance of the a-c coils. This is not an exact statement of the necessity, however, because the phenomenon of flux leaking from

Figure 5. Another type of reactor construction



the saturated core into the air is not very closely equivalent to the flux which would link the coils if the core were entirely absent.

Now it is possible that someone in the near future will devise a simple method of taking leakage flux properly into account. The authors, as we have seen, have really taken it into account, in a way which seems to give satisfactory results, by using the measured saturation curve for the core. The limitation which must be kept in mind is that the saturation curve, however measured, is not a saturation curve for the magnetic material, but a curve for the complete structure, and that any change in configuration of the core or coils will probably bring about a significant change in the saturation curve, even though the material of the core is not changed.

Even the curve for a toroidal core is not entirely the same as the curve for the material, because even in a toroidal winding some flux flows around the outside, inside, and at both axial ends of the core which may link the winding without ever entering the core.

If the ampere-turn-per-inch values are relatively low, the leakage flux may still be negligible. In a reactor with the a-c coils in parallel, the magnitude of the a-c ampere-turns is approximately instantaneously equal to that of the d-c ampere-turns, and it is quite possible that the leakage flux produced by these ampere-turns may be small for a particular reactor, especially one of low power. For one of much higher power, however, the leakage flux cannot be even approximately neglected. It is not quite clear from the example given in the paper whether the leakage flux (roughly equivalent to air-core inductance of the a-c coils) is negligible.

In devices in which the linear relation between d-c and a-c ampere-turns is important, the leakage flux presents an even more difficult problem, because it effectively prevents linearity by introducing a very considerable effective constant inductance in series with the a-c circuit.

The leakage of d-c flux is probably nearly as important as leakage of the a-c flux, but can be reduced to reasonably small values by the use of the double-core reactor in which the d-c coil is closely coupled to the a-c coils, as in Figure 5 of the discussion. (United States Patent Number 2,374,059.) Other means of accomplishing the same result are known.

One other interesting conclusion follows from the fact that the effective saturation curve for a magnetic material does not necessarily represent the curve for the reactor. In order to take proper advantage of the high-permeability materials which are supposed to be the secret of success in magnetic amplifier construction, very careful consideration must be given to elimination of leakage flux paths. The authors show very clearly too that the fast-breaking saturation curve, even if it can be obtained, does not result in a reactor with significantly different characteristics from that with a slow-breaking curve. Evidently the specialized materials will not be either as useful or as essential as might be thought.

Tests were made on a 30-kva saturable core reactor. This reactor was of the two separate core type, with the a-c coil in parallel. Table I gives a comparison of the direct current needed for various alternating currents and voltages. The calculated direct current was determined from the test excitation curve.

Table I. Test and Calculated Performance of a Saturable Core Reactor

30 Kva, 480 Volts, 62.5 Amperes, Alternating Current

Volts, alternating current	Amperes, alternating current	Calculated I_{DC}	Test I_{DC}
543	60.3	1.00	1
387	50.2	1.00	1
171	40.4	1.12	1
102.6	30	1.05	1
74.3	65	2.10	2.3

The correlation between calculated and test values are within engineering accuracy. If curves for $b = 0.25$, 0.35, and 0.4 were given, the usefulness of the curves would be increased, although if I_b were chosen when making the tests so that I/I_b were always less than 0.7, the curves would be adequate.

The limitations of this paper are not really basic. The problem of calculation of reactor performance has not been solved by the authors for all possible connections of this type of reactor, and probably never will be. The authors have devised a general method, of which this paper demonstrates only one application. The general method, however, should be applicable to many other problems, and this paper should certainly be studied carefully by all those who intend to design or to apply saturable reactors, with the thought that this general method will probably be the fundamental basis for eventually complete design literature.

L. A. Finzi (Carnegie Institute of Technology, Pittsburgh, Pa.): W. C. Johnson and his associates attack the problem of the performance of magnetic amplifiers in terms of the true variables defining the operation, that is the average core flux and the crest value of the alternating superposed flux. The fitting of the normal *B-H* curve with an analytical function is a very skillful one. Another, somewhat similar analysis has been made by my associates and myself at Carnegie Institute of Technology. We have fitted the experimentally obtained normal *B-H* curve of the core materials with a power series, and also with combinations of hyperbolic sines, and from these we have obtained expressions for the current, which in each case checks with the experiment, with the same order of agreement as Johnson obtains. We have also obtained a satisfactory agreement in somewhat more involved cases, such as amplifiers with external feedback or with self-feedback. Here disturbing phenomena as "commutation" occur during the cycle. As D. W. VerPlanck reported at the National Electronics Conference at Chicago in 1948, the feed-back winding cuts itself loose during the cycle from the output circuit and behaves as a winding, short circuited through the rectifiers. This phenomenon complicates the analysis, since the instants in the cycle at which commutation begins and ceases, have to be determined by matching at boundaries, and so forth. In this case, too, our analysis checks surprisingly well with the experiments.

The agreement reported by the authors, and that which we have also found, leads to the conclusion that the basic simplifying assumptions (that is sinusoidal flux, use of normal *B-H* curves, and so forth) are sound, and that the general method of attack is correct, at least for silicon steel, and similar materials. In any case the analytical fit of the *B-H* curve has to be close over the whole range of operation, extending far above the knee. Less careful fitting, as has been suggested in some old German literature (for example, by means of a single hyperbolic sine), does not seem adequate. On the other hand, the function chosen should lead to expressions for the currents that are easy to compute numerically. The author's analysis leads to gamma-functions, while our analysis leads to modified Bessel functions, both of which are tabulated.

The studies to which I refer have appeared as Report Number 5 in a series of reports prepared at Carnegie Institute of Technology under United States Navy Contract.

I should like to add a further comment. The authors mention the fact that the average flux of the core, with superposed alternating magnetization, is lower than at first expected. In our experimentation, we have observed that small values of the alternating magnetization may cause a small increase of the average flux as reported by T. Spooner.[1] This is a phenomenon also which does not seem to be related to the circuitry of such nonlinear elements; and can probably be explained in terms of the structure of the magnetic material. For the cores used in our experiments (hypernik) this phenomenon was not important enough to modify the basic analysis, but it would be of interest to hear whether this has been found more important for different core materials.

W. C. Johnson, B. C. Merrell, and R. E. Alley, Jr.: We wish to thank the discussers for their interest in the paper and for their many helpful comments. Storm's presentation of oscillographic evidence of the depression of d-c flux is convincing and very pertinent. In this laboratory we have made calculations recently of similar transients in saturable-reactor circuits and find good agreement between calculated and experimental results. We hope to report on this work in a later paper.

Wentz and Specht are quite correct in pointing out that our analysis takes account of flux which leaves the iron and passes through the air. It is necessary here to distinguish between two uses of the term "leakage flux". It may mean all the flux which passes from the iron into the air, or it may mean the portion of the above-mentioned flux which links one winding, but not both. Our analysis takes account of the flux which links both windings, regardless of its path. However, it does not take into account the flux which leaks between the coils and links only one winding. The latter was what we meant when we stated the assumption relating to our neglect of "leakage flux."

Experiments indicate that our analysis, based though it is on a sinusoidal variation of flux, is surprisingly good under load conditions with a rather high series impedance when the flux is certainly not sinusoidal at all. Therefore, this assumption seems not as restrictive as might be thought. This is certainly reassuring, for one needs to simplify these nonlinear problems just as much as possible in order to make the results at all usable.

We are aware of the excellent results obtained by VerPlanck and Finzi and their associates, and are glad for this opportunity to acknowledge their work.

The analysis which we present in this paper represents our third attempt to find a reasonably simple and usable presentation of the results of our original work. Alley's first analysis of the problem was presented in his master of science thesis in the spring of 1940. Our results at that time were as correct and accurate as those we have finally presented in this paper, but they required rather laborious calculations. We have spent considerable time and effort in simplification, and feel that it has been time well spent. The problem of presenting the results of a nonlinear analysis in useful form is a difficult one indeed.

Microwave Channels for Power System Applications

AN AIEE COMMITTEE REPORT

THE microwave system is a very high frequency beamed radio channel for transmitting information from point-to-point. It was highly developed during the war and promises to become a valuable tool to electrical power systems as a channel for the transmission of information which it is desired to send from point-to-point in the normal operation of the system. Relaying, telemetering, supervisory control, and communication are functions which could use such a channel. The information required by these functions now is being sent over pilot wires and power line carrier channels for the necessary communication media. The microwave channel, by virtue of its air-line transmission, and the large number of quantities which can be transmitted from point-to-point on a single beam, opens up application possibilities which cannot be handled with present methods. Spectrum crowding of power line communication channels has occurred. In most cases of spectrum crowding, considerable communication traffic of one kind or another exists and the installation of a microwave channel may easily be justified. While microwave channels will in some cases be used to replace pilot wire and power line carrier channels their major advantage will probably lie in supplementing existing methods and thus extending the possibilities of the use of communication channels for the transmission of intelligence necessary to obtain better power system operation.

Characteristics of Microwaves

Microwaves are radio waves in the region from a few hundred megacycles up. These correspond to wavelengths from about 100 centimeters down. For example, the 10-centimeter and 3-centimeter waves used in radar are considered to be microwaves. Radio waves of these short wave-lengths travel generally in a straight line like light and cannot be picked up if intervening objects such as hills, buildings, or the curvature of the earth interfere.

A line tangent to the surface of the earth rises to a height of $0.66S^2$ feet where S is the distance in miles from the point of tangency. For example, the line of sight would be 66 feet above the surface of an assumed perfectly spherical earth at a point ten miles from the point of tangency. As this height varies with the square of distance, it would be 264-feet above the surface when 20 miles away. Thus it would be theoretically possible to go about 35 miles line-of-sight between two 200-feet towers. It may be necessary for the line of the microwave beam to clear the nearest obstruction by some 50 feet. Tests show this is too conservative but this safety margin should be retained for the time being. Adding this 50-foot clearance, the tower height required on the average for different transmission distances is indicated in Table I. It would be possible to transmit approximately half this distance with only one tower of the indicated height and the other antenna 50 feet above the earth.

From Table I, it will be seen that a pair of towers a little over 100-feet high are good for 20 miles and towers about 200-feet high are good for 30 miles. These are average figures and in many cases favorable terrain will make much greater distance of transmission feasible and the converse is also true.

The number of microwave communicating channels which can be used is dependent on three factors:

1. Line-of-sight characteristic.
2. Angular directional characteristic.
3 Frequency selection.

Fifty miles away from a given installation, the line-of-sight of that installation would be 1,650 feet above the earth's surface and the same frequencies could generally be used over again. Thus the entire available spectrum may be thought of as being available in each 100-mile-square area. However, a great many channels could be used at the same frequency because of the directivity of the pattern. In other words, the antennaes are directional to a fairly high degree. Taking a conservative figure of 20 degrees, it is entirely possible that four signals could be sent in four directions from a given point without interfering, although reflections from buildings will need to be considered. There are several frequency bands which are available on an experimental license basis for power system applications using microwaves some of which are for commercial use (power, gas, water and steam utilities) some for government use, and some for joint use as shown in Table II.

For the purpose of an example for this report, consider the band from 952 to 960 megacycles. Channels could be spaced 100 kc apart, and there would be 80 such channels using the 8-megacycle band mentioned. It is easy to demonstrate with a hypothetical system the relatively enormous number of channels that a microwave system can provide. For example, a given 100-kc channel could be occupied by a microwave carrier together with modulation of the microwave carrier at audio (or modulated subcarrier) frequencies. Assume that six communication channels (voice channels) can be accommodated in each 100 kc of band

Paper 49-5, recommended by the AIEE carrier current committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31-February 4, 1949. Manuscript submitted October 12, 1948; made available for printing November 29, 1948.

This report of the AIEE carrier current committee was prepared by S. C. Leyland, manager, relay engineering, Westinghouse Electric Corporation, Newark, N. J.

Table I. Average Distance of Microwave Transmission with Two Towers of the Indicated Height

Half This Distance for One Tower with the Other Tower 50 Feet High

Transmission Distance, Miles	Required Antenna Height*
5	54
10	67
15	87
20	116
25	153
30	199
35	252
40	314
45	385
50	462

(Based on spherical earth with line-of-sight always 50 feet minimum above the surface.)

*Note: If the effective earth radius is four thirds the actual radius, an approximation to account for the bending of the rays around the earth, then the antenna height required is three quarters of the values shown.

width. These channels can be used for voice only, or a combination of voice and about four audio tones, or for about ten audio tones without voice. Using these figures, a single microwave channel can accommodate 6-voice and 24-tone channels, or a total of 60-tone channels without voice. See the summary in Table III.

This illustrates that in the 952-to-960-megacycle region, 1,920 voice channels or 19,200 audio tone channels could be made easily available in each 100-mile-square area. This may be compared very roughly with a saturation limit of the order of 30-voice channels or 300-tone channels available over power line carrier. Roughly 60 times as many channels are available with the microwave and they can be repeated oftener. In addition, the higher frequency microwave bands will accommodate more audio channels than the 952–960 megacycle band.

Advantages of the Microwave System

Channel Reliability. A microwave channel is as reliable as the atmosphere through which transmission takes place. It is not dependent on the continuity of transmission line conductors or pilot wires for reliable operation. Microwave channels would not be subject to the same degree to conditions such as sleet, windstorm, airplane damage, and so forth, which might render wire channels inoperative.

Facilities per Channel. The intelligence required by a large number of different functions can be transmitted on a single microwave channel using modulated subcarriers as described. The maximum number of channels which can be provided is dependent on the type of multiplexing equipment used. Time division multiplexing, for example, will make many more channels possible than the use of subcarriers only. Therefore the number of channels or facilities per channel is very flexible and the type of multiplexing equipment used will largely be determined by economic factors.

Freedom from Interference. Interference in the microwave band is very small and may even be a negligible factor. This is true both from the standpoint of the microwave channel interfering with other facilities, and of other facilities or external interference, interfering with the microwave channel. An exception might be interference caused by an airplane flying directly in the path of the beam near one of the antennas. Rain and snow do not noticeably affect transmission in any of the lower frequency bands. However, frequencies in the order of 10,000 megacycles are subject to atmospheric absorption and refraction, and their variations cause attentuation and fading, but suitable safety factors may be possible with adequate design.

Maintenance. Since the microwave channel and terminal equipment are independent of the power system, maintenance can be performed without the necessity of having any part of the power system out of service. This simplifies and makes safer the maintenance problem particularly in those cases where in a carrier installation, maintenance on the coupling capacitor or line trap is necessary.

Disadvantages of the Microwave System

Line-of-Sight. The necessity of line-of-sight will have a number of disadvantages associated with it. In some cases it will necessitate repeater stations and the reliability of power supply at this repeater must be assured.

Power Supply. The higher voltage requirement necessitates the use of an a-c power supply with any equipment foreseen for some time. This is no particular disadvantage for some uses but for others, where reliability is of particular importance as in relaying, it will be necessary to use a continuous d-c to a-c power supply unit in order to use station battery power. In other communication and telemetering installations, it will be necessary to have transfer equipment to go over on the battery in event of loss of the a-c supply at the station.

Structure Rigidity. There may be a problem of directivity and loss of contact due to deflection of the antennae or structures upon which they are mounted. It is believed, however, that with a comparatively broad beam, this factor can be kept under control. Construction cost of suitable structure for mounting the antenna may be high.

Table II. Present Frequency Assignments for Point-to-Point Service

Band	Megacycles	Type of Service
952	960	Commercial
1,700	1,850	Government
1,850	1,990	Commercial
2,110	2,200	Commercial
2,200	2,300	Government
2,400	2,700	Commercial
4,400	5,000	Government
6,575	6,875	Commercial
7,125	8,500	Government
9,800	9,900	Commercial and Government
9,900	10,000	Commercial
12,200	12,700	Commercial
13,200	16,000	Government

Possible Applications

In view of the advantage and disadvantages of microwave channels as compared to power line carrier or wire channels, the following application possibilities are typical:

Telemetering. A microwave channel provides an ideal means of transmitting a large number of telemetered quantities from point-to-point. This would be particularly valuable for those locations where line-of-sight is possible from the load dispatcher's headquarters to one or more different points on the system, and carrier or wire facilities are not available for accommodating the large number of quantities desired.

Supervisory Control. Application requirements similar to those necessary for telemetering channels also would make microwave channels attractive for the transmission of a large number of super-

Table III. Possible Channels in Each 100 Mile Square

Item	Number
Direction	4

Total	19,200
or	
Voice and tone combination	5
Total	9,600
or	
Voice alone	1
Total	1,920

visory control functions from point-to-point.

Relaying. For locations where a large number of circuits exists between two points on a power system, and all the relaying requirements for the transmission of intelligence can be served by a single microwave channel. In this category would be stations interconnected by power cables, where the use of a carrier or pilot wires would not be possible or economical.

Communication. Important communication facilities necessary for dispatching purposes where other kinds of channel were not considered economically or technically possible.

Combined Services. It is expected that microwave channels will be most effective where large numbers of different types of intelligence must be transmitted between points on a power system or from the system to the load dispatcher's office. Combinations of telemetering, supervisory control, relaying, and communication will be the more common, but other services such as transfer tripping, teletype, telegraph, and load control, would be possible users of the microwave channel.

Part of a Communication Network. It is expected that the use of microwave channels in conjunction with existing or contemplated carrier or wire channels will greatly increase the utility of these channels by extending the scope of the entire communication system.

Conclusions

It is quite apparent from the economic and engineering possibilities of this system, from its successful use during wartime, and from the general interest in it throughout the country by responsible individuals that this field will definitely develop. It will occupy part of the place now occupied by carrier but will probably never displace carrier completely, and it will open new fields which are not now economic by carrier or wire channels. It will also provide power companies with an increased opportunity to control their own communicating facilities for important dispatching services and control functions.

Discussion

R. F. Stevens (Bonneville Power Administration, Portland, Oreg.): As the first power utility to adopt microwave radio as a major part of its communication network, the Bonneville Power Administration (BPA) has an especial interest in the appraisal of this new tool by the carrier current committee.

The conclusions agree well with those of our own studies on this subject, which we started immediately after the war, and which resulted in the purchase in 1948 of equipment for four microwave stations. These stations, plus three others, should be in operation by the end of 1949, and will form a multichannel link, 200 miles in length, connecting our Portland-Vancouver headquarters and dispatchers' offices with points in the Puget Sound area. This system operates in the 1,700–1,850 megacycle band using pulse time modulation. The network will be extended later to other important centers in our region.

The decision to use microwave was based in part on the crowding of the carrier spectrum, which had become quite serious. Careful cost comparison between carrier and microwave, based on typical conditions on our system, provided an equally compelling argument. The curves, shown in Figure 1 of the discussion, prepared from these studies show rapidly increasing savings from use of microwave as the number of channels along a given route is increased beyond four. On the other hand they indicate saving for carrier where but one or two channels are required. This has led us quite naturally to a decision to use microwave for our backbone communication routes, and carrier for radial branches. It also has provided confirmation for the opinion of the carrier current committee that microwave is not likely to completely supplant carrier at any time in the near future.

While our curves should be applied with caution to other situations, where basic conditions are different, the same general pattern can be expected; namely, a comparatively constant cost per channel for carrier and a high-minimum cost and low-incremental cost per channel for microwave.

It also should be remembered that the cost of power line carrier is pretty well stabilized, whereas the cost of microwave is likely to decline as development costs are written off and greater production is achieved.

Our comparison is based on microwave equipment which can be expanded to provide 23 or more channels relayed through many stations in tandem. We feel there is a definite field also for simpler and less expensive equipment for perhaps 2-, 3- or 4-voice channels. Such equipment would be used for links of short over-all lengths, or for short branches from the main microwave link, and need not meet the same distortion limitations necessary where many relay stations are in tandem. Such equipment also might open to microwave part of a field which we, in our thinking, have assigned to carrier.

ADDITIONAL ADVANTAGES OF MICROWAVE SYSTEM

The following advantages might be added to those listed in the paper:

Superior Voice Quality. A well-designed microwave system provides an extremely flat frequency response even though the signal must pass through many relay stations in tandem. This permits better voice quality; also successful multiplex transmission of a greater number of telemetering signals over a single voice channel. Attainment of comparable quality is impractical in many carrier installations.

Microwave Provides Full 2-Way Communications. Power-line carrier systems often must use the same frequency in both directions to conserve spectrum. This requires use of a push-to-talk switch or a voice relay. In contrast, standard microwave systems permit simultaneous 2-way transmission.

Availability of Wide Spectrum. In contrast to the crowded carrier spectrum, the available microwave spectrum is tremendously wide.

Use with Fixed-to-Mobile Radio. A microwave system can be connected readily to, and used in conjunction with, very high frequency radio stations transmitting to mobile units. Very high frequency transmitters can be installed at microwave relay tower sites, which are usually well suited to the purpose. Access roads and power supply lines can be used in common.

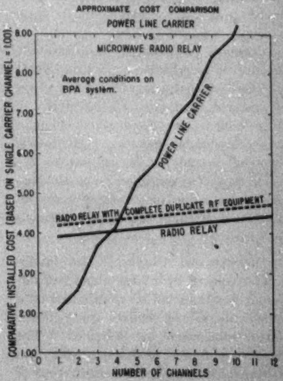
Use During Construction. Microwave stations can be installed in advance of transmission lines and used during the construction period at a power project.

Low Incremental Cost when more Channels are Needed.

ADDITIONAL DISADVANTAGES OF A MICROWAVE SYSTEM

More Eggs in One Basket. Trouble in the radio-frequency, or in parts of the multiplexing equipment may involve many channels and thus be more serious than failure of a single-carrier channel. This will become less serious as life expectancy of tubes and other parts is improved. Further, this dis-

Figure 1.



advantage can be overcome, at price, by duplicate equipment or duplicate routes, with automatic cut-over. In this case channel reliability will be better than for carrier.

The three other disadvantages listed in the paper can be overcome by proper design and by paying the necessary cost. The cost of overcoming these disadvantages is included in our comparison with the carrier.

Applications. Our plans for use of microwave confirm the prediction of the committee that it will find its greatest application where many different types of intelligence are to be transmitted over a given route. Of the applications suggested (telemetering, supervisory control, relay and communications, teletype, telegraphy, and load control) we will eventually use all (except perhaps teletype and telegraphy) and will add one or two additional uses. One of these may be facsimile. A more novel use planned is for instantaneous transmission line fault location using a system developed at BPA and described in a paper published in 1948.[1] The theory is very simple and is based on the fact that a transmission line fault sends travelling waves down the line in both directions at the speed of light. With the aid of a single timing pulse sent over the microwave system, the difference in time of arrival of these travelling waves at opposite ends of the line will be measured, from which the distance to the fault in miles will automatically be computed and printed on a chart.

Power Line Relaying. We believe that application of microwave to power line relaying offers more than the mere substitution of one type of channel for another. New approaches to the whole power line relaying problem become possible when it is not necessary to assume that the signalling channel may be out of service at the time of a transmission line fault. It should be possible to decrease by a significant amount the time required to clear both ends of a faulted line, and thus to permit also faster automatic reclosing. Preliminary studies indicate the resulting gain in stable transmission power limit may in itself alone justify a heavy microwave investment. This subject is being actively studied by BPA.

Layout of Beam Paths. Table I of the paper is of interest in indicating the distance between stations which might be expected under average conditions. It is often possible to take advantage of terrain. However, mountainous country is often less favorable than flat country, due to intervening hills or ridges that always seem to appear at the wrong places. For the 200-mile BPA link, the longest distance between stations is 54 miles. The average length of path is 32 miles with short branches respectively 12 and 15 miles in length. The average tower height is 96 feet. The two highest towers will be 145 feet high. Ground elevations at the towers vary from 180 feet to 1,980 feet. Most sites in our region above 2,000 feet in elevation, as well as really high points such as Mt. Hood, Mt. St. Helens, and so forth from which great distance can be seen, are impractical as radio sites due to lack of accessibility for roads and power. Most commercially developed equipment also lacks the power output at present to take advantage of extremely long paths.

Opinions seem to vary as to whether actual earth radius or the four-thirds value should be used in laying out beam paths. The paper makes no recommendation, other than that a 50-foot clearance between beam and intervening terrain, and suggests that this may be found conservative.

Based on experience reported from a prominent eastern installation, and on a desire to be conservative on our first installation, we have used true radius and a minimum clearance of 100 feet in our design work.

Since the most adverse conditions in the propagating medium may occur at very rare intervals, operating experience over a long cycle of years may be necessary before we can determine definitely whether we have been more cautious than necessary.

While tower height is not the major item in the over-all cost, it is still an important one. Lower towers result both in lower first cost and in more convenient and less costly maintenance. More complete studies and advance test data which will permit more exact determination of minimum tower heights therefore are needed.

Line Tuning Equipment Used With Coaxial Cable for Carrier Current Installation on Power Lines

HOWARD J. SUTTON
ASSOCIATE AIEE

THE ADVANTAGE of using low-loss coaxial cable in conjunction with power line carrier equipment has been recognized for some years. The use of this cable has made it possible to locate the carrier transmitter-receiver near the equipment associated with it, rather than out near the capacitor which couples the carrier signal to the power line. Coaxial-cable connections have made carrier installations much more flexible than was possible before this type of cable was used.

Although the advantage of using coaxial cable has been known for some time, very little information has been published relative to its use for power company installations. A lack of knowledge on the part of the user makes it difficult to obtain the best operating adjustment of the equipment, or to select the most economical equipment. It is the purpose of this paper to discuss some of the theoretical and practical problems pertaining to the use of coaxial cable. The paper will be limited to the connection between the transmitter-receiver and the coupling capacitor, and to carrier current by-pass circuits.

To understand the behavior of coaxial cable, we must consider this type cable as a network rather than a simple conductor. As shown in Figure 1, this network is made up of series impedance branches and shunt admittance branches.

The resultant series impedance branch is equal to

$$Z=R+j\omega L \qquad (1)$$

The resultant shunt admittance branch is equal to

$$Y=G+j\omega C \qquad (2)$$

The values R and L represent total resistance in ohms and total inductance in henries of the cable used, while the values G and C represent the total shunt conductance in mhos and shunt capacitance in farads of the same cable.

The network or cable has a characteristic or surge impedance, Z_o, equal to

$$Z_o=\sqrt{\frac{R+j\omega L}{G+j\omega C}} \qquad (3)$$ [1,2]

On short lengths of low-loss cable, 1/12 wave lengths or less, the R and G values may be neglected without changing the results appreciably and equation 3 becomes

$$Z_o=\sqrt{\frac{j\omega L}{j\omega C}} \text{ or } \sqrt{\frac{L}{C}} \qquad (4)$$

The characteristic impedance is an important value when considering a network. A network terminated in an impedance equal to its characteristic impedance will also have an input impedance equal to the characteristic impedances and there will be no standing or reflected waves encountered in the network. In simpler terms a coaxial cable terminated in any value other than its characteristic impedance will introduce distortion or higher losses in the circuit. The amount of distortion or loss is dependent upon the length of cable compared with the wave length of the carrier frequency and the magnitude and type of load on the end of the cable. A coaxial cable with a characteristic impedance of 65 to 70 ohms is usually used for carrier applications.

Sometimes it is desirable to terminate a cable in an impedance different from the characteristic impedance, see Figure 2. When this is the case the impedance as seen at the sending end, Z_s, of a low-loss coaxial cable terminated in an impedance of any magnitude or type, Z_R, can be determined from the following equations

$$R_e=\frac{Z_o^2R}{(Z_o\cos\beta 1-X\sin\beta 1)^2+(R\sin\beta 1)^2} \qquad (5)^*$$

$$X_e=Z_o\frac{(Z_o^2-X^2-R^2)\dfrac{\sin 2\beta 1}{2}+Z_oX\cos 2\beta 1}{(Z_o\cos\beta 1-X\sin\beta 1)^2+(R\sin\beta 1)^2} \qquad (6)^*$$

Where

$$Z_s=R_e+jX_e \qquad (7)$$

$Z_o=Z_c=$ characteristic impedance of cable
$Z_R=R+jX=$ terminating impedance
$\beta_1=$ electrical length in degrees
$\beta_1=\frac{1}{\lambda}\times 360$ degrees (λ for coaxial cable is approximately 55 per cent of value in air)

From equations 5 and 6 it can be seen that when

$$Z_o=Z_R, \text{ and } Z_R=R_R+j0 \qquad (8)$$

$$Z_s=Z_R=Z_o \qquad (9)$$

Equation 9 is then in agreement with a statement made previously that when a network is terminated in its characteristic impedance, the input impedance will also be equal to the characteristic

Paper 49-6, recommended by the AIEE carrier current committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted October 13, 1948; made available for printing November 29, 1948.

HOWARD J. SUTTON is with the Gulf States Utilities Company, Beaumont, Tex.

The writer wishes to acknowledge and express his appreciation for the helpful comments and suggestions made by N. L. Jacklein, A. P. Cummins, E. W. Kenefake of the General Electric Company; J. M. Nelson and S. C. Leyland of the Westinghouse Electric Corporation; and to R. O. Hopkins and W. W. Eckles of the Gulf States Utilities Company.

*Equations 5 and 6 from E. W. Kenefake, General Electric Company, Schenectady, N. Y. These equations hold true for a dissipation less line or low loss cable, and can also be derived from the following equation appearing in another publication[1]:

$$Z_s=Z_o\frac{Z_R+jZ_o\tan\beta 1}{Z_o+jZ_R\tan\beta 1}$$

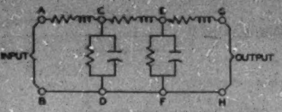

Figure 1. Equivalent coaxial cable network

impedance. Calculations were made at various frequencies for two sample lengths of coaxial cable (195 feet and 1000 feet) with terminating impedance of $Z_R = 500 - j10^6/2\pi f \times 0.003$ and the results were plotted as curves, see Figure 9. A study of equations 5 and 6 or the curves will indicate that the difference between the apparent input impedance Z_s and the terminating impedance Z_R becomes greater as the length of the cable increases. In the case of the 1,000 foot cable the capacitance load at the terminating end appears as an inductive load at the sending end at 150 kilocycles.

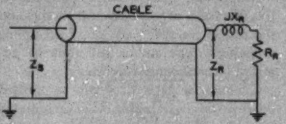

Figure 2. Schematic diagram for equations 5 and 6

The previous discussion has pointed out that coaxial cable should be considered as a network and has given formulas for calculations. Before studying several different coaxial transmission circuits, consideration should be given to the type of circuit a power line presents to radio frequency. For simplicity, only carrier coupling to a single conductor with ground return will be discussed. A single conductor will introduce resistance and inductance. In addition the shunt capacitance to ground will be an appreciable value. The power line can also be broken down into a network as shown in Figure 1.

The characteristic impedance of a line can best be determined by tests. From tests made on the Gulf States Utilities system the characteristic impedance has been found to be between 300 to 600 ohms. The coupling between the conductor connected to the carrier and the other conductors of the line plus the coupling between other lines makes it very difficult to calculate the impedance from equation 3.

Three different types of coaxial transmission circuits will be discussed. To assist in the description, the circuits will be called types *A*, *B*, and *C*.

Type A Circuit

The type *A* circuit as shown in Figure 3, may be used with coaxial cable without limitation at carrier frequencies. In this circuit the tuning inductance is adjusted so that its reactance is equal numerically to the capacitive reactance of the coupling capacitor. By the above tuning, the condition of connecting *G* directly to *J* is approximated. The surge or characteristic impedance of the power line is assumed to be 500 ohms.

A transformer *EFGH* is used for matching the line impedance to that of the cable. Winding *EF* is connected to the coaxial cable. The connection to *GH* winding is varied so that the 500-ohm load appears as a 70-ohm load across the *EF* winding. The coaxial cable is then matched to its characteristic impedance and maximum efficiency or low attenuation is obtained.

A carrier by-pass circuit similar to the foregoing circuit would be connected as shown in Figure 4. Carrier by-pass circuits are used when it is desired to provide a low-impedance circuit around one or two circuit breakers (one of which might be opened) or a power transformer bank. For this circuit a tuning inductance is provided on each end of the circuit to cancel out the reactance of the coupling capacitors. Both of the impedance transformers are connected so as to present 70-ohms load on each end of the coaxial cable.

In order to obtain a comparison between the type *A* line tuning circuit as shown in Figure 3, and the other two types to be discussed, tests were performed using three different lengths of coaxial cable, 61 feet, 195 feet and 1,000 feet. The results of these tests were plotted as curves, see Figures 10, 11, and 13. These curves show the total loss in the circuit in decibels at various frequencies from 30 to 150 kilocycles. For tests, a coupling capacitor of 0.003 microfarad was used in series with a 500-ohm resistance load. The 500-ohm load represents a high-voltage transmission line. These curves show the type *A* circuit to be the most efficient except at the highest frequency.

In addition to the type *A* circuit being the most efficient, it has the additional advantage of presenting very nearly a resistance-type load to the carrier transmitter throughout the frequency range.

The chief disadvantage of the type *A* circuit over the other types to be discussed is the cost of the equipment and the additional cost of installing the equipment. In the case of the carrier by-pass the additional cost is doubled because the coaxial cable is terminated at each end in a type *A* circuit, see Figure 4. Refer to Figure 16 for typical type *A* line tuning equipment.

Type B Circuit

This coaxial transmission circuit is the same as the type *A* circuit, see Figure 5, except the line tuning inductance (*GI*) of Figure 3 is omitted. The apparent impedance of the line shown in Figure 5 is then $(500 - j/\omega C)$ ohms. The value of 500 ohms is the assumed characteristic impedance of the power line. *C* is the capacity of the coupling capacitor in farads. To tune this circuit the connection to winding *GH* is varied so that the load on this winding appears as a 70-ohm load across the *EF* winding.*

In the case of a carrier by-pass, the circuit will be the same as type *A* circuit, see Figure 6, except both line tuning in-

---

*The impedance matching transformers used for the tests had two separate windings with a powdered iron core. Winding *EF* was designed for use with 70-ohm cable. The other winding or secondary has a range of 70 to 1,900 ohms. The transformers had very low losses between 50 and 150 kilocycles.

ductances will be omitted. The tuning of the by-pass circuit will be same as described in the previous paragraph.

Since the reactance of the coupling capacitor has not been cancelled by a tuning inductance, the cable will be terminated in a load with a high capacitance component which might be objectionable. Because of this fact, the use of the type *B* circuit is limited by the capacitance of the coupling capacitor and the length of the coaxial cable. From tests made it has been found that the type *B* circuit can be used in a frequency range of 75 to 150 kilocycles if the capacitance of the coupling capacitor is 0.00275 microfarad or greater, and the coaxial cable does not exceed 400 feet in length. Under these conditions, the capacitive component of load will be sufficiently low to be used with a typical carrier transmitter and the losses will be only slightly different than that of the type *A* circuit.

The tests indicated that the impedance matching transformer in transforming from a high impedance to a low impedance decreased the capacitive component, which meant that the cable was terminated in a load of a lower capacitive component than would be expected. The tests also indicated that the type *B* circuit could be successfully used between a frequency range of 100 to 150 kilocycles if the capacitance of the coupling capacitor was 0.0015 or greater and the cable 400 feet or less in length.

The type *B* circuit is much more economical to install than the type *A* circuit. The impedance matching transformer is mounted in the base of the coupling capacitor, see Figures 14 and 15. It is therefore necessary to provide only a conduit from the transmitter to the base of the coupling capacitor. The advantage of the type *B* carrier by-pass is even more pronounced because only mounting details for the two coupling capacitors and a path for the coaxial cable must be provided.

A reference to curves Figures 10, 11, and 13 will show that the losses of type *B* circuit, when used as recommended in the preceding paragraphs, are not enough greater to warrant the added expense of the type *A* circuit. Another advantage of the type *B* circuit is that one setting of the impedance transformer will pass a wide band of frequencies with very little difference in losses. A double frequency type *A* tuner might be required to pass the same band of frequencies.

Type C Circuit

This type circuit is connected as shown in Figure 7. The equivalent circuit is shown in Figure 7A. In this case the tuning inductance is located inside in the transmitter-receiver cabinet. This circuit will be tuned when sufficient inductive reactance is added to counteract the capacitive reactance as seen at the sending end of the coaxial cable. When tuned, the load on the transmitter will appear as a resistance load.

As an example, refer to curves shown on Figure 9 for the sending end impedance, Z_s, of the 195 feet cable for 50 kilocycles. From the curve $Z_s = 62 - j404$ ohms. If an inductive reactance of $+j404$ ohms is inserted in series, then the transmitter should be adjusted for a 62-ohm resistance load. If we should consider the transmitter end as the receiving end of the coaxial then $Z_R = 62 + j404$ ohms. The $+j404$ figure is the reactance of the line tuner and 62 ohms is the approximate impedance of the transmitter. Substituting the above values of Z_R in equations 5 and 6, we find that $Z_s = 500 + j1060$ ohms. Referring to Figure 7 the impedance of the cable circuit at *I* will be $500 + j1060$ ohms. Under the condition specified for curves Figure 9 the impedance of the line at point *I* will be $500 - j10^6/2\pi f \times 0.003$ or at 50 kilocycles it will be $500 - j1061$ ohms. The inductive reactance of the cable will then cancel the capacitive reactance of the coupling capacitor. The circuit will then be adjusted for maximum efficiency.

The use of type *C* circuit is limited because the coaxial cable is not terminated in an impedance approximately equal to its characteristic impedance. This fact is evident from the example given in the previous paragraph. Because this circuit is not matched with the cable, the problem of distortion from reflected waves becomes more troublesome as the length of cable increases, or as the frequency increases. If the use of this circuit is confined to short lengths of cable, approximately 200 feet or less, or to low frequencies, 100 kilocycles or less, the behavior of the coaxial cable will approximate that of a simple conductor. The amount that the foregoing range can be extended is dependent upon the impedance of the coupling capacitor and on the amount of distortion which can be tolerated.

The type *C* by-pass circuit is connected as shown in Figure 8. Inductance *AK* is adjusted so that its reactance will counteract the reactance of capacitor *AC* and likewise inductance *JI* is adjusted to counteract capacitance *JL*. If care is exercised in adjusting the circuit one of the foregoing inductances might be omitted.

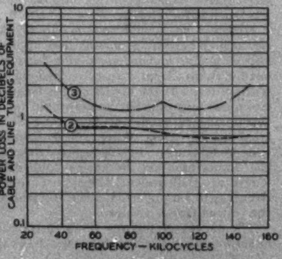
3. Type *C* by-pass circuit refer to Figure 8 except only one tuning inductance used. *CC1* and *CC2* = 0.003 microfarad



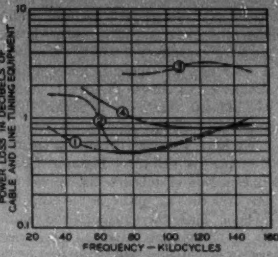


Figure 13. Loss curves for line tuning equipment with 1,000 feet of coaxial cable

Load $= Z_R = 500 - j10^6/\omega \times 0.003$ except for curve 4

1. Type *A* line tuning
2. Type *B* line tuning
3. Type *C* line tuning
4. Same as curve 2 except $Z_R = 500 - j10^6/\omega \times 0.0015$

The advantage of the type *C* circuit over the type *A* circuit is in the cost of equipment and installation. The type *C* circuit can be used in the lower frequency range where the type *B* circuit should not be used. This circuit also presents a resistance load to the transmitter whereas the type *B* presents a load with a capacitive component. As stated previously the use of the type *C* circuit should be limited to short lengths of cable 200 feet or less and to low frequencies 75 kilocycles or less. A reference to loss curves, Figures 10 and 11, will show that in the recommended range of use, the type *C* circuit compares favorably with the type *A*. With the 1,000 feet of cable, Figure 13, distortion was so pronounced that points for 30 and 50 kilocycles were not plotted. The losses for the remaining frequency range were much greater than for either the type *B* or type *A* circuits. A comparison of losses between the type *B* or type *C* by-pass circuits is shown in Figure 12.

Combination of Type B and Type C Circuits

By the addition of a line tuning coil inside the transmitter receiver cabinet the range of use of the type *B* circuit can be extended. The objection to the capacitive component to the transmitter can also be removed.

Summary

The tests providing the basis of this paper were performed in an effort to determine the best type of carrier by-pass to use on our line between Beaumont, Tex. and Baton Rouge, La. An effort was made to determine how much line tuning equipment was required for various installations. The tests were also made to eliminate considerable field work in making adjustments.

Upon the basis of our tests we have decided to use type *A* carrier by-pass circuits in phase "A" of our line for our communication circuit between Beaumont and Baton Rouge. This carrier will operate on two frequencies of 51 and 68 kilocycles over a 132-kv line through coupling capacitors of 0.0015 microfarad. A reference to comments under type *B* circuits or to curves Figures 11 and 13 will indicate that type *B* circuit should not be used for this application.

We have, however, decided to use type *C* by-pass as shown in Figure 8 for the transmission of telemetering carrier signals over the "C" phase of the same 132-kv line. These carrier channels are in the 30- to 34-kilocycle band. The required tuning inductances will be located in the same cabinet as the equipment for the type *A* circuit.

In an 85-kilocycle carrier communication circuit between Beaumont and Navasota, Tex., we have installed and had in operation for nearly a year a type *B* by-pass circuit. This by-pass is in the circuit at all times since wave traps are used to prevent the carrier energy from being dissipated in the substation. The by-pass is on a 69-kv line using 0.003 microfarad coupling capacitor. The connecting coaxial cable is approximately 200 feet long.

We have had several type *B* line tuning carrier relay circuits in operation for several years. Two terminals are on the 69-kv lines using 0.003 microfarad coupling capacitors. The cable lengths are under 100 feet and the frequency over 100 kilocycles. The balance of the type *B* circuits are on 34.5-kv lines. The longest length of cable is 330 feet.

It is hoped that this paper might stimulate other papers on the same subject and that information of value may be obtained from this paper and other papers to be written.

Discussion

H. W. Lensner (Westinghouse Electric Corporation, Newark, N. J.): Sutton has presented an interesting paper which includes some valuable data on limitations of frequency and cable lengths for various simplified line tuning systems. The simplification in equipment and adjustment as described is obtained at the expense of flexibility in choice of frequency, however, and as more carrier channels are added to a power system, the problem of frequency allocation becomes more complex.

Modern carrier transmitters using pentode or beam-power output tubes operate best when fed into a resistive load. The reactive termination presented to the transmitter with the type *B* tuning system can cause considerable harmonic output which may interfere with other services. This would not be of much consequence with unmodulated carrier which operates only occasionally, such as for relaying.

However with amplitude-modulated carrier at high percentage modulation, appreciable distortion and accompanying harmonic output results from a reactive load on the transmitter. At the higher carrier frequencies now in use, the harmonics would fall in the broadcast band, and with tone-modulated carrier telemetering, severe interference would result. In this respect, although the limitations on frequency and cable length are still present, the type *C* tuning circuit is to be preferred, since the load on the transmitter is resistive.

The curves of Figures 10 to 13 indicate losses which are considerably lower than that of other published data.[1,2] This raises a question as to the method of measurement of losses[2] and whether all the losses of the circuit elements were included.

The writer has made tests on a line tuning system similar to the type *B* circuit of Figure 5. The impedance matching transformer, however, was designed to have enough reactance to cancel the capacitive reactance of the coupling capacitor. By means of a few taps on the secondary side, it was possible to provide a reasonable impedance match and still present an essentially resistive load to the carrier transmitter over the carrier frequency band. Several of these units have been installed in the field with coaxial cable lengths up to 1,000 feet, and are giving dependable performance. Laboratory tests on the units including 1,200 feet of coaxial cable gave a total loss of from

0.9 to 1.6 decibels for a 0.004 microfarad coupling capacitor and 1.6 to 2.2 decibels for a 0.00129 microfarad capacitor. Even with the reasonably good impedance match, cancellation of reactive component and resulting reduction of standing waves provided by this special matching transformer, the measured loss figures are higher than the results shown in this paper.

The simplified tuning systems seem to be particularly well suited to use as by-passes around a transformer bank or open circuit breaker, especially if two or more frequencies are to be transmitted through them. The elimination of a multiplicity of tuning coils and trap circuits makes the systems described especially attractive.

H. J. Sutton: The writer wishes to express his appreciation for the comments made by Lensner. The primary purpose in presenting the three types of circuits was to bring out the characteristics of coaxial cable circuits in a discussion of practical applications. As a secondary consideration, the type *B* and type *C* circuits were recommended for limited applications.

Lensner, in his discussion has brought out some of the objections to the use of the simplified tuning circuit, particularly the type *B* circuit. The writer perhaps did not emphasize sufficiently that the impedance matching transformer used for the tests of this paper added inductive reactance which partially overcame the capacitance of the coupling capacitor. In the range recommended for the use of the type *B* circuit, the load on the transmitter was very close to unity power factor, and no trouble should be experienced from harmonics or distortion.

The tests were made in a laboratory using mica coupling capacitors rated at 2 500 volts direct current. No drainage coils or lightning arrester gaps were included in the tests. Otherwise the tests included all losses present on actual installation. The following instruments were used:

Thermo-coupled milliammeters, ±5 per cent accuracy.

(Note all milliammeters checked against standard and correction factor used.)

Vacuum tube voltmeter, ±2 per cent accuracy.

Cathode-ray oscilloscope, to check wave form and phase angle.

Electronic switch, to check phase angle. Possible ±10 per cent accuracy.

Considering the instruments used, a possible error of 5 to 10 per cent or 0.2 to 0.4 decibels may be present in the actual losses. A comparison of the differences in losses, type *A* and type *B* circuits, as shown on curves Figures 10, 11, and 13 agrees within 0.2 decibel of differences in coaxial cable losses as obtained from the manufacturer's published losses. The loss curves were used for comparison between the three circuits, and for this purpose the possible error in results would not make any appreciable differences in our conclusions.

Shipshaw Relay Protection

J. T. MADILL
MEMBER AIEE

F. H. DUFFY
ASSOCIATE AIEE

Synopsis: This paper will describe the relay protection of the Shipshaw Number 2 Generating Station of the Aluminum Company of Canada, Limited, and will draw attention to particular points of interest in design considerations and will outline some operating results and experience. In particular the excellent performance of one type of generator winding protection will be outlined. This protection has established a new record by detecting faults at a stage earlier than recorded hither-to-fore in the literature. In general this paper will illustrate modern protection for a large-unit type hydroelectric generating station.

AN ELEMENTARY 1-line diagram of the station will be seen in Figure 1. The basic design is the unit system; one 75,000-kva 13.2-kv generator, one 90,000-kva transformer bank, one 2,500-000-kva high-tension circuit breaker, and one 154,000-volt transmission line, with no low-tension or high-tension busses between units. In the case of the center six units, minor modifications are made for local and auxiliary power supply, but still no interconnection exists, because of interlocks. Almost the total output of the 1,200,000-horsepower Shipshaw Number 2 Station is transmitted at 154,000 volts, just two miles to the Arvida aluminum ingot production works.

Most of the relay protection is located on the back of the unit duplex switch boards, on the front of which the unit meters are mounted. Figure 2 shows the relays of one unit, and Figure 3 shows one unit diagrammatically. The most important sections of the protection are indicated on this latter diagram.

The ordinary generator percentage differential protection extends from the neutral leads to the phase leads of the generator. Both sets of current transformers have a ratio of 4,000/5 amperes and are the bus-bar type. Instantaneous balanced-beam percentage differential relays having two restraining coils, one in series with each set of current transformers, and one operating coil, connected between the junction of the two restraining coils and the neutral lead, are used. These relays are connected on their most sensitive tap, and will operate with a minimum of 80 milliamperes unbalance or 1.8 per cent of full load current. They have a 2.5 per cent characteristic, that is at any current, a difference of 2.5 per cent between the line and neutral currents will cause the relays to close contacts. This percentage protection was used because it was of the high-speed type, not the induction-time type, and was very sensitive.

It was believed that the transformer protection, while better than most, was not fast enough at low currents, or sensitive enough, for the generator, and the split-phase protection was untried.

The eight parallels of each generator phase are connected in two groups of four each, and leads are brought out from each group as shown in Figure 3 to permit the application of split-phase protection. These leads are brought in opposite directions through the two primary windings of the split-phase current transformers, which have a double primary and single secondary winding. The ratio is 500/500/5 amperes. The balanced-beam instantaneous overcurrent relays connected in the secondary circuits are set to have a minimum operating current of 0.5 ampere which is 1.3 per cent of full load current.

Figure 4 shows one split-phase current transformer. The double-primary, single-secondary construction permits very sensitive relay settings because there is no unbalance between current transformers. Currents are bucked against each other in one transformer and only the difference flux produces secondary current. Therefore saturation or burden present no problems and cannot cause false operation. Twenty-five amperes circulating between the winding halves or 50 amperes unbalance between the halves will cause these relays to close contacts. With a generator maximum current of 3,750 amperes, this gives a sensitivity of 1.3 per cent. Though the current transformer nominal ratio is 500/500/5 amperes, each half of the transformer is rated at 2,000 amperes continuously, and when connected in series on test, with a current of 3,000 amperes flowing, the maximum acceptable secondary current is 0.05 ampere. This current is of such small magnitude that normal generator unbalances due to design and construction details become the limiting factor in the relay settings.

The generator standby, or phase protection is connected to three Y-connected 4,000/5 ampere bus-bar type current transformers located on the generator neutral leads. The voltage-restrained inverse-time overcurrent relays, of the induction-disk type are calibrated to have a minimum operating current of 4.0 amperes and an operating time of 135 cycles at eight amperes with voltage restraint. This provides a setting of about 70,000 kva. With the voltage restraint this is increased to about 105,000 kva which provides ample margin for load currents. From Figure 5 it may be seen that it is necessary for this protection, to clear phase-to-phase faults on the low-tension side of the step-down transformer bank at Arvida, and this influences the settings. This standby protection must be able to operate on the sustained short-circuit current of one isolated generator which in the case of large hydroelectric generators, may not be much in excess of the load current. For the case under consideration, the minimum fault current which must be detected is 132 per cent of full load current. One of these relays is shown in Figure 6.

Paper 49-7, recommended by the AIEE relay committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted October 27, 1948; made available for printing December 13, 1948.

The low-tension neutral or generator 13.2-kv ground relay is connected in the neutral of the Y-connected 4,000/5 ampere standby current transformers. It is an instantaneous balanced-beam type overcurrent relay. The operating current is 0.5 ampere or 11 per cent of full load. With the neutral point of the generator solidly grounded, this ground relay covers the transformer bank low-voltage winding, the 13.2-kv bus and all of the generator winding coils, with perhaps the exception of those particular coils connected right at the neutral point. It provides fairly sensitive, high speed, duplicate protection on the 13.2-kv equipment at just the cost of the relay and hence is easily justifiable.

The transformer bank or over-all differential protection extends from the generator neutral leads to the line side of the high-tension circuit breaker. The current transformers on the high-tension side are the bushing-type with a 600/5 ampere ratio and are delta connected. The second set is located, for convenience and extra protection, on the generator neutral leads. These current transformers have a normal ratio of 4,025/5 amperes and are tapped to exactly match the transformer bank turns ratio on each transformer tap. Also their saturation characteristics were designed to match those of the high-tension type. The characteristics of these current transformers are such that under the worst condition, a fault immediately outside of the high-tension circuit breaker, the transformers are operating well below the knee of their saturation curve and false tripping is definitely avoided.

The relays are the induction-disk low-energy very inverse-time overcurrent type with instantaneous overcurrent attachments, which have a better characteristic for transformer bank protection than the percentage type relays.

Figure 7 shows on the same co-ordinates, the time curves of a differentially-connected induction-type overcurrent relay with an instantaneous attachment, a high-speed transformer percentage differential relay set on its lowest tap, 25 per cent, and an induction-type transformer percentage differential relay. For severe faults the two former relays both operate in one cycle. The minimum operating current for the percentage relay is two amperes, while that for the induction-type overcurrent relay is 0.5 ampere. This latter relay is therefore four

times as sensitive as the percentage relay and does not have the complications of voltage or harmonic restraint. Many installations do not operate the percentage relays on the lowest ratio, consequently the sensitivity may be even poorer. It should also be noted that as many windings and/or connections, from either the high tension or the low tension, as desired, can be accommodated with the overcurrent relay system, whereas the percentage relay is definitely limited in this regard.

This principle is used at Shipshaw and at other stations on the Saguenay system to prevent faults on local and auxiliary power supply systems at generator voltage, from tripping the transformer differential protection falsely. Of course, no scheme is better than the current transformers used, regardless of the relays.

There was no object in not including the generator in the transformer differential zone, as there are no low-tension circuit breakers. Four sets of current transformers are located together on one capacitor bushing on the generator neutral leads. Thus extra protection is available for the generator at no extra cost.

The price of the induction-type relay is about one-sixth of the percentage relay and in an installation involving 36 relays this is of some interest. The simplicity and reliability of this relay make it very desirable. The induction element is set to operate at 0.5 ampere which is 11 per cent of full load current and to have a time delay of 15 cycles at 2.5 amperes. The instantaneous attachment is set at 10 amperes or 200 per cent of full load. It might be noted that the 11 per cent setting was the most sensitive transformer bank differential relay setting reported in an AIEE survey made during 1946. This differential protection has never tripped falsely for faults just outside its zone, even though voltage recovery may impose some magnetizing transients on the relays.

An exactly similar installation is used at a station which has a low-voltage bus. Here transformer banks are energized at full voltage from either the high-tension or the low-tension side and no trouble with false tripping is experienced from either the time or instantaneous elements. No other type of protection is as suitable for covering a complete zone from circuit breaker to generator.

The high-tension neutral, or transformer bank ground relay is operated by a 100/5 ampere current transformer connected between the transformer bank Y-point and ground. The inverse-time overcurrent relay has a minimum operating current of 2.35 amperes, that is, 15 per cent of full load. The time delay is set at 45 cycles at 11.75 amperes. From Figure 5, it may be seen that this time delay is necessary to provide selective clearing of faults on other lines connected to the same section of the Arvida high-tension bus. The faulted line will be cleared from the system by ground relays at Arvida in 10 cycles on a 60-cycle base, and therefore the time delay in the Shipshaw ground relays is permissible. From Figure 5 it may be seen that the transmission line protection could only be solved, as far as the generating station is concerned, as it was, or by pilot wire or carrier current relaying, and either of the latter two would have to be considerably

more complicated than in the case of an ordinary 2-terminal line. Because of the short lines, carrier current did not seem attractive and it developed that pilot-wire relaying, because of cost and reliability, was not selected either. This was because the high ground fault currents and rocky terrain required lead covered cable, and a 1,900-foot river crossing made this difficult. It was considered too risky to put the protection for all 12 lines in one cable, and without this the cost of the line protection became about 40 per cent of the cost of the transmission line itself. This is very difficult to justify, bearing in mind the bus arrangement already in existence to a large degree, at Arvida. There were no suitable commercial telephone channels available for lease. Therefore ground relaying and phase standby protection were used. This was relatively low in cost, simple and reliable, and has given satisfactory results.

Each transformer at Shipshaw is equipped with a gas detector relay of the Bucholz-type having a gas accumulation element, which operates an alarm, and a pressure element which operates one of the trip relays. The relay is located as shown in Figure 8, on the top of the transformer proper, and at one side for convenience of access during service.

The generator a-c overvoltage protection is provided by a solenoid self-resetting relay connected to a 13,200/110-volt potential transformer. The relay operates at 114 per cent voltage to energize a light and bell circuit, and through a contactor to add resistance to the field circuit of the main exciter.

The pilot exciter d-c overvoltage relay is energized directly by the output voltage of the pilot exciter. It operates at 120 per cent of normal pilot exciter voltage to insert a block of resistance in the field of the pilot exciter and thus limit the voltage to 120 per cent of normal under almost any overspeed condition.

The generator field ground detector is a solenoid-type relay connected between the center tap of a high resistance and one side of a 110-volt 60-cycle circuit. The resistance is connected across the generator field leads and the other side of the 110-volt circuit is connected to ground. The relay is set to operate with about 0.5 ampere ground current and covers the complete d-c circuit to which it is connected. This protection only operates an alarm.

The turbine overspeed consists of a centrifugal device on the permanent magnet generator which operates mercury switches to sound an alarm and energize the trip relay at 130 per cent speed.

Figure 9 shows the d-c control circuit for all of the relays which have tripping action. It may be seen that some sensitive and some high-speed protection for both the generator and transformer bank is connected to operate each trip relay. That is, the generator differential operates one trip relay, the split-phase protection the other. The transformer differential energizes one while the standby operates the other trip relay. Two trip relays were used so that the failure of one trip relay coil, mechanism, or contacts would not make all of the protection inoperative. Hand reset relays were used because of their simplicity in construction and in associated wiring, and because of their reliability.

All d-c circuit sources are separated back to the main d-c bus, but there was no alternative to paralleling the two trip relays, since both must energize the same coils.

All relays are calibrated annually using a test board which contains a cycle counter and meters of suitable range for current and/or voltage indications on each relay, as well as a switch arrangement to facilitate the use of the instruments. A very careful check of minimum operating currents and time setting is made, all dust or dirt particles removed, and any worn or defective parts replaced. This calibration, properly made, requires two men for $2^1/_2$ to 3 hours for each Shipshaw unit.

Annual relay calibration records for five years show that for the induction-type relays a change greater than 2 per cent may be expected in the minimum current setting in five relays per one hundred relay years, and a change in time setting of more than one cycle in 4.8 relays per one hundred relay years. In the high-speed type relays there is no apparent deviation in operating time, but the minimum current setting may be expected to change more than 2 per cent in 2.7 relays per one hundred relay years. The variation outside this 2 per cent figure is still only of the order of 6 per cent.

Turning now to operating experience, the gas detector accumulation elements have detected ten incipient low-tension winding joint failures, as reported previously[1] long before total failure. Complete confidence is placed in these elements and it was decided that their operation has been so excellent, and has indicated the trouble at such an early stage, that a check of all transformers is not justified. In other words, operating experience has led to the conclusion that

Figure 10. Hot joint in neutral ring bus detected by split-phase relay

Figure 11. Turn-to-turn coil fault involving only two turns detected by split phase relay

Figure 12. Turn-to-turn coil fault on generator detected by split phase relay

complete reliance in these elements is justified. There have been no faults for the pressure elements to detect, but to-date this element has never caused a false trip. With proper technical supervision and sampling devices there is no difficulty in interpreting indications from the gas detector accumulation elements.

Upon several occasions, rheostat trouble caused the loss of field on one 75,000-kva generator, when loaded to about 65,000 kw. This loss of field was always picked up by the relay protection, though no element was particularly designed for this. If the field decay took place rather slowly, the armature current in the generator, because of decreasing voltage, increased sufficiently slowly to permit the back-up or phase relays to close contacts and trip the unit. Under this condition, the generator remained in synchronism until tripped. If, however, the loss of field was more abrupt, the generator lost synchronism before the phase relays could close contacts. In this case the overspeed switch operated almost immediately upon the loss of synchronism and tripped the unit.

Including construction difficulties, there has been a total of eight troubles which may be classed as internal generator faults. At the same time, there has been accumulated at Shipshaw about 62 generator years or $4^{3}/_{4}$ million kva years of operating experience.

The split-phase protection operated on every one of the eight internal generator troubles. Three of the faults were to ground or phase-to-phase and other protection, such as the generator differential, or low-tension-neutral operated during the same cycle. One fault was a turn-to-turn one which broke down to ground but was detected so rapidly by the split-phase protection that no other relays operated. Four faults could be detected only by the split-phase relays.

One of these four was a hot joint in one neutral ring bus of one generator. The joint resistance finally unbalanced the winding currents and operated the split-phase protection. This fault is shown in Figure 10. Considering that this was in the neutral bus of a solidly grounded generator, it is difficult to see how any other protection could possibly have detected this fault until it had developed to the major proportions of a serious fire and/or a phase-to-phase bus short circuit.

Three of the four faults were turn-to-turn short circuits detected only by the split-phase protection. The machine was tripped without any system fault occurring and without any internal fire or arc or burning. In two different generators these turn-to-turn coil faults have been detected by the split-phase relays. The generator has been tripped off the system with no apparent fault jar, or arc, or burning, or ground. In both cases, the coils have been located and changed without a break occurring through the coil insulation. A simple and reliable method has been developed by which the faulty coil is determined, and thus no iron is burned and no other coils are damaged. Obviously this is the ideal condition as there is the minimum possible fault damage. As far as is known this has not been done before on a large-capacity solidly-grounded generator. This protection has been most satisfactory. Figure 11 shows the first signs of one fault as the coil insulation was being removed. About half the coil side insulation had been removed at this point. Figure 12 shows one fault in one coil, which involved only two of the three turns.

Checks on split-phase currents have indicated that the maximum unbalance in any generator is about 28 amperes or 0.75 per cent. The average unbalance of the 36 phases is only about 14 amperes or 0.37 per cent. Thus, it may be seen that the designers have done an excellent job of balancing the windings.

So far, no false trips can be definitely attributed to this protection, though one case is suspect. However, several definite experiences have shown stability or non-operation of this protection for through faults. In one, a fish wire established a double-line-to-ground fault on the 13.2-kv leads from one generator to its transformer. This was detected by the low-tension neutral and by the transformer

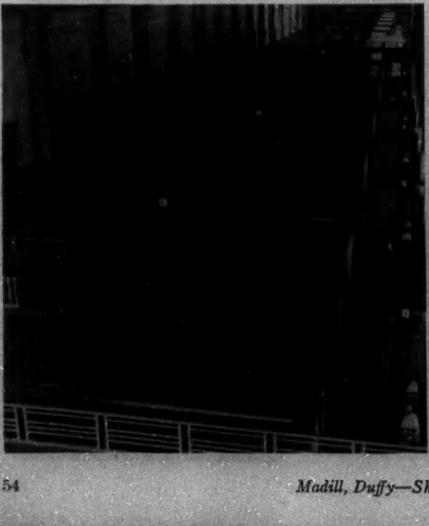

Figure 13 (left). Interior view of Shipshaw powerhouse

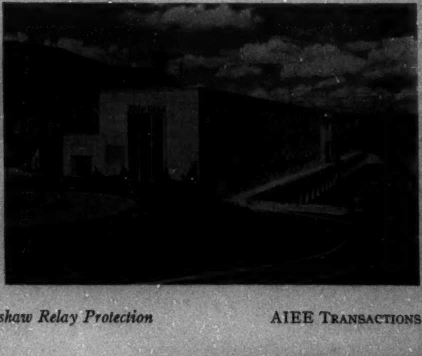

Figure 14 (below). Exterior view of Shipshaw powerhouse differential relays, but the generator split-phase relays did not operate. The fault current supplied by the generator was about 10,300 amperes. In another case, a dead line-to-ground fault occurred six feet outside of one high-tension oil circuit breaker. This was detected by the high-tension neutral relay and no other protection operated. In this case, the bank supplied about 1,150 amperes to the fault. In any future station of the unit type, it is thought that with split-phase generator protection, and with transformer differential protection which includes the generator, no percentage generator differential protection would be necessary. This would eliminate two sets of current transformers and one set of relays. However, Shipshaw Number 2 station was one of the first applications of this type of split-phase protection and it was felt that the percentage differential relay was desirable. In summing up, the following points stand out:

1. On the Saguenay system, with the very short lines and with the bus system as installed at Arvida, the rather simple combination of the back-up or phase relays and the transformer bank high-tension neutral relays have handled the line faults adequately.

2. The relays used have maintained their settings excellently and have been very reliable.

3. The transformer gas detector protection has given results far better than anticipated and has proved to be extremely valuable. This protection should always be used on any conservator-type transformer over 6,000 kva rating. The transformer differential has not been called upon to operate for winding faults, but has detected any faults in its zone and has not operated falsely for faults immediately outside of its zone.

4. The back-up or phase relays, combined with the overspeed trip have proved a reliable combination to detect loss of synchronism, and in turn loss of field. Some element of the generator relay protection should always be capable of detecting this latter condition.

5. The generator split-phase protection has been the outstanding feature of the generator protection. Its ability to detect turn-to-turn coil faults, and series faults as well as all of the usual short-circuits, has not been available previously. It is of the high-speed 1-cycle type and is very sensitive, 1.3 per cent. It has never missed an internal unbalance and has not operated falsely. This protection is most highly recommended.

Therefore, in conclusion, it would seem that by a judicious choice of relay methods, some of which were relatively new and untried, combined with a careful co-ordination of current transformers, and careful balancing of generator winding design, excellent protection has been secured with relatively simple elements, and is retained by careful, systematic maintenance.

The magnitude of the development on which this protection has been applied may be judged by Figure 13 which shows the generator room and Figure 14 which shows the Shipshaw Number 2 Station.

Discussion

D. A. McKenzie (The Hydro Electric Power Commission, Toronto, Canada): We have been very much interested in the paper presented by Madill and Duffy on Shipshaw Relay Protection. The schemes selected are simple and reliable, and in view of the perfect performance record it would seem that nothing further could be asked in the way of protection. We should be glad, however, to have certain points clarified.

Differential Protection for Generators

While it would appear from the information submitted covering actual performance that the differential protection for the generators (percentage type) is faster than the over-all differential protection on the generator and transformer, as might be expected from the types of relays used; it would appear that this protection could safely have been omitted as has been suggested by the authors.

Split-phase Protection for Generators

Since generator protections based upon the similarity of the currents in circuits of multicircuit windings have been used for many years, we must assume that the statement that the "Shipshaw Number 2 station was one of the first applications of this type of split-phase protection" refers to the use of the special 2-primary current transformer. This type of current transformer, with normally zero secondary current, should of course, provide more sensitive and stable protection than could be expected from schemes in which standard current transformers are used and their secondary currents combined. However, some sensitivity is lost by the necessity of combining the circuits into two groups (to suit the 2-primary current transformer) since current could still circulate between the circuits without leaving the group.

It would be understood from the reference to 36 phases that the unbalances referred to have been obtained on the secondaries of the special 2-primary current transformers, but no mention is made regarding the load on the generator at the time these unbalances were measured. While balance between the two groups of circuits per phase is very good, this does not preclude the possibility of circulating currents between the circuits of the group. It might be mentioned that on several generating units which have recently only been placed in service, the circulating current between the two groups has been of such magnitude that the sensitivity of this type of protection has been very seriously affected.

It would have been expected that this protection would have functioned so rapidly in all cases that no other protective scheme could have indicated operation. Would it be probable, that in the cases where the generator differential or the low-tension neutral schemes functioned, the fault current reached high values very quickly?

Mention is made of an operation of this protection for a hot joint in the neutral ring bus of a generator. It would be of interest to know the exact location of this joint, that is, whether it was in the connection of one of the circuits to the group bus or in the connection of the group bus to the lead to the neutral.

Differential Protection for Generator-Transformer Group

This protective scheme should provide very satisfactory protection against faults within the zones covered by its current transformers, especially when combined with the split-phase protection which, of course, only covers the generator.

It is not quite apparent from an inspection of Figure 7 how the comparisons between the three types of relays which were considered for this protection, were obtained.

Loss of Field Protection in Generators

The interest in protections to function on loss of field has been developing during the past few years and the occurrences at this plant indicate that this matter requires serious attention. It would appear that an additional protection to provide high-speed operation is required. It should be feasible to provide more sensitive protection than the back-up relays and faster protection than the overspeed protection.

Generator Neutral Grounding

The fact that there are no interconnections at generator voltage is, of course, most favorable to the direct connection of the generator neutral to ground.

The employment of a current transformer in the neutral connection, of a suitable range, would have provided a more sensitive and stable ground protection than the residual current from the three 4,000/5 ampere current transformers installed for the standby relays.

It is interesting to note that no burning of iron has been experienced with the neutrals connected directly to ground.

It would have been of interest to have employed the recently developed method of grounding generator neutrals through a suitable capacity service-type transformer, on some of the generators in this plant to obtain comparative information on performance. In view of the apparent high incidence of faults in these generators, comparative information could be obtained in a relatively few years. This method provides sufficient current to enable reliable and fast operation of the protective schemes to be obtained and yet limits the fault current to values which will not result in burning of the iron. Moreover, by proper selection of the resistance burden on the transformer secondary, resonance is prevented and the scheme provides all the advantages of the dead grounded neutral with none of its disadvantages.

Overspeed Protection on Generator Unit

It is noted that the overspeed protection is mechanical, a centrifugal device within the permanent magnet generator, supplying power for the drive for the governor flyball head.

The setting of 130 per cent of normal speed for this protection seems somewhat low for use on hydraulic turbines but in view of the layout of this station and its type of load, it is probable that unnecessary operations of this protection would not be objectionable. Would the authors state how many operations of this protection have been experienced even if in conjunction with other protective schemes? Would they also advise if the shutdown solenoid of the governor operates through the governor valves, or if there is any provision for high-speed closure of the gates? In view of the independent drive on the governor head, it would be expected that the governor would be adequate to take care of overspeeds due to loss of load on the unit and that this device would not add to the plant security in such cases.

It is suggested that since the tachometers on these turbine governors are undoubtedly voltmeters calibrated in terms of speed, the simplest and most reliable overspeed protection would be obtained by use of a suitable overvoltage relay. This relay could be checked for operation at will and its setting changed as desired.

The maintenance and adjustment of the mechanical overspeed protection is an expensive and somewhat hazardous matter.

Overvoltage Protections on Generator Unit

The detector for grounds on the generator field is of a type which has given excellent service for many years.

The protections against overvoltage on the pilot exciter and on the main generator a-c winding are, of course, desirable in plants designed for normal service and it is of interest that even in this rather specialized plant it has been considered desirable. The functioning of the a-c overvoltage protection to add resistance in the field circuit of the main exciter appeals to us as fast and reliable but we should be glad to know if provision is made for this element to reset automatically.

Transformer Protection—Gas Detector Relays

The record of operations of the gas-detector relays installed on these large transformers is of very special significance, particularly when the method of installation of the relay is considered. The relay is shown mounted at the extreme edge of a large flat top surface which must have supports beneath it, and unless some means has been provided within the transformer to collect any gas generated and direct it to the location of the gas-detector relay, it would seem probable that only a very small percentage coverage in the matter of gas collection is obtained. Even the small opening in the cover adjacent to the relay probably would collect many times the amount of gas required to operate the relay before any gas would find its way to the relay. Also the openings in the cover leading to the conservator tank and to the explosion vent would provide means for the gas to escape without proceeding to the relay. Therefore, the detection of ten incipient cases of fault is an amazing performance, especially since none of the faults had progressed to the point where the operation of the transformer was affected. However, it would be quite reasonable to assume that many similar faults can be progressing and we would feel that a careful check on all transformers would be justified and at the earliest possible date. While it is necessary to locate these relays so that they may be inspected and reset, when desired, with the transformer remaining in operation, we believe that the importance of this type of protection will justify either the employment of several of these relays properly located on the top of the transformer, or the use of some means within the transformer to ensure that a fairly high percentage of any gas generated will be directed to the gas-detector relay. In the employment of this latter expedient, care must be taken that the entrance of the pressure wave to this relay is not impeded. If a single relay is employed, the European practice of mounting it on the connection to the conservator tank would appear to have considerable merit, even though some of the sensitivity of the pressure wave element would be lost.

It is noted that these relays have not yet been required to function on an actual case of trouble in a transformer. From a considerable amount of experience with these relays, it may be reliably expected that this protection normally will function in advance of the differential protection even of the sensitivity employed in this station on actual faults within the transformer. Even failures of high-voltage bushings have been cleared by these relays.

It has been a pleasure to study a paper such as this which shows evidence of such careful study of the various factors involved, and which frankly admits to an astonishing number of faults.

A. W. Rauth (Consumers Power Company, Jackson, Mich.): This paper discussing the relay protection of the Shipshaw Hydro Station is well written and interesting. In addition it shows how a relay problem is solved, and it should have far reaching value in demonstrating what can be done when full co-operation is obtained from everyone concerned. This has special reference to co-operation in solving protective problems pertaining to generation, distribution, and transmission.

The Shipshaw Station as demonstrated by the paper is one of the largest hydro stations of the world. It therefore required considerable study and ingenuity to make sure that the best type of equipment was used that such equipment was protected by the simplest, most effective protective scheme, and that the scheme was one which required the least amount of maintenance for the protection received. The operating results as given in the paper clearly show that all three of these things were accomplished. It also shows that the scheme of protection used could have been accomplished only by the complete co-operation of the protective engineer, the design engineer, the equipment engineer, and the operating engineer. This certainly should be an example of one method of solution to all major electrical protection problems. Perhaps those concerned with relay problems should be complimented in being able to obtain the results indicated in the paper.

In solving many protective problems pertaining to electrical transmission, distribution, and generation, it would appear that at times the design and equipment engineers complete their job and then ask the relay engineer or protective engineer to apply his ingenuity in protecting the equipment so that good service is maintained. The result in many cases is that the protective engineer must resort to highly specialized, complicated schemes which require considerable attention and frequent testing and calibration to provide adequate protection. The Shipshaw protective scheme clearly illustrates that important protective problems involving the protection of large generating stations can be solved by a simple, inexpensive protective scheme requiring practically no maintenance. The important thing is that the scheme used even though simple, provides better protection than some of the more complicated highly-specialized protective devices.

Without question, to my mind it seems that this is one of the outstanding power generating installations which clearly demonstrates what can be done with a simple protective scheme, if the protective engineer is given an opportunity to use his ingenuity before the generating and distribution designs are completed. It also illustrates that the thinking of the protective engineer is just as important as that of any group of engineers in designing generating or transmission systems.

F. L. Lawton (Aluminum Company of Canada, Montreal, Canada): Having been closely associated with the Saguenay system from the days when the Isle Maligne hydroelectric generating station was under construction, and with the design and construction of Shipshaw Number 2 power plant, it will not be inappropriate to comment briefly on the paper and certain of the points mentioned by previous discussers.

The authors have described the Shipshaw relay protection and the results achieved, results which surpass anything hitherto obtained with large hydroelectric generating stations, particularly as regards the split-phase feature. It should be emphasized that the excellent performance is due to full co-operation between the owner's engineers, fully conversant with system background, the consulting engineers responsible for design, and the manufacturers' engineers from the early stages of design. The relatively simple but well-balanced protection, properly designed and installed initially, has been well maintained, with the optimum performance noted.

The decision to solidly ground the generator neutrals stems from past experience on the Saguenay system. The generators at the 12-unit 450,000-kva Isle Maligne hydroelectric generating station were originally operated with isolated neutrals. Differential protection consisted of the type available in the early 1920's, differentially-connected current transformers and so-called instantaneous plunger-type solenoid relays.

Although single-phase-to-ground faults, with isolated generator neutrals, involved negligible burning of stator iron, some 50 per cent of all such faults developed into multiphase faults, frequently with excessive damage to stator iron.

As a result, groups of generators were operated in parallel at generator voltage and were arranged so that one generator in a group would be grounded through a neutral resistor of moderate value. Percentage differential relays were installed. This resulted in improved relay performance and a decrease in multiphase winding faults but too much burning of stator iron still occurred during such faults.

Thus our thinking was oriented over a period of years towards solid grounding of generator neutrals to eliminate multiphase faults, to sensitive and reliable differential relays which could detect low-fault currents, and to generator field circuit breakers to minimize duration of fault current after the quick-acting differential relays had operated—hence the generator protection adopted at Shipshaw with solidly-grounded generators. However, provision was made for the installation of generator neutral impedances should experience warrant their installation.

It may seem to some, for our stated experience with gas-detector relays at Shipshaw, that we have had an excessive number of faults with the 36 single-phase step-up transformers. Actually, all the troubles have been of a similar nature, that is, defective brazing of the heavy cable connections between the two low-tension windings. This defect appears to have resulted from poor workmanship by one individual which was not picked up by the factory inspection. In any case, there have been no actual faults (only incipient faults) all detected well in advance of actual failure, so that the transformer in question could be removed at our convenience without an interruption to service.

In fact, our experience with gas-detector relays at Shipshaw, and elsewhere on the Saguenay system, is such that we are convinced no large power transformer (5,000 kva and over, of the conservator type) should ever be installed without a gas-detector relay. Ours certainly have paid for themselves many times over.

Reference has been made to the short 154-kv transmission lines (two miles) connecting Shipshaw Number 2 generating station and the load center at Arvida. This voltage was decided on for two reasons: first, because the Saguenay system had been planned for 154 kv, and second, because far less strategic materials were required during the war emergency.

H. P. Dupuis, D. C. Harker (Commonwealth and Southern Corporation, Jackson, Mich.): The authors are to be congratulated on the excellent presentation of the application of the split-phase differential relay scheme for the protection of generator armature windings. It has long been recognized in the relay art that it is difficult to obtain protection of faults near the generator neutral by the usual current-differential scheme. Although the split-phase scheme of generator protection is not new, it is gratifying to learn that it has shown such an excellent performance record. The detection of a hot joint in a generator neutral ring even before it becomes a fault is indeed noteworthy. Similarly, turn-to-turn faults have been exceedingly difficult, if not impossible, to detect by conventional schemes before breakdown to ground occurs, with resultant possible serious and costly burning of the generator stator iron. The split-phase scheme of protection is, therefore, to be commended particularly for its ability to detect these faults so rapidly that in most cases the machine is tripped before any disturbance to the system occurs, and without any internal fire or burning; in fact, for two of the cases cited, even before any breakdown occurred in the coil insulation. Since there has been no false tripping due to the unusual sensitivity of the scheme, it appears that the split-phase arrangement of generator protection approaches the ideal for large vertical waterwheel generators. It would be interesting to know whether the split-phase scheme has been, or could be, applied to high-speed turbo-alternators where space and turn limitations enter into consideration.

Of particular interest is the ingenious method of using two current transformers having a common magnetic circuit to balance any saturation effect. Also of considerable interest is the excellent record of the gas-accumulator relay for the protection of transformer faults. This augments the present splendid record for this type of transformer protection, and perhaps may be instrumental in extending the application of this type of relay in the United States.

Eight generator faults out of 12 installed units in approximately five years appears to be an unusually high record of field trouble for this type of equipment. Presumably, this is due to war-time manufacturing conditions. However, it causes some concern to contemplate what loss of vital aluminum production during the war years might have resulted had not the split-phase scheme provided such adequate generator protection.

One cannot agree with the implication that $4^3/_4$ million kva-years is indicative of long experience, because so many kilovolt-amperes are involved. However, it is hoped that the continued use of the split-phase scheme of generator protection will prove to be as satisfactory as the experience so far has indicated.

The paper points out that a saving in cost of the relay installation is achieved by using induction-type instead of percentage relays, and in this particular installation there are probably factors which warrant the use of the less expensive type of relay. Where alternate relay schemes provide equal protection, the least expensive and simplest probably should be chosen. However, if one scheme provides better and more complete protection than is obtained in another, then other factors being equal, it would seem that the amount of money which could be spent justifiably on protection is a function of the value of the equipment to be protected; that is, buying relay protection is similar to buying insurance.

It is noted that the output of the Shipshaw Number 2 generating station is transmitted at 154 kv to its load at Arvida, only two miles distant. It would be helpful to know the factors leading to the choice of this particular voltage. Perhaps, too, a very brief description of the connections and relaying at the Arvida terminal would be of assistance to relay engineers in obtaining a better overall picture of the back-up relaying.

The magnitude of the power involved is impressive. In looking at the interior view of the power house, one realizes that he is looking at a concentration of generation sufficient to supply the entire requirements of many of the larger power systems in the United States.

F. H. Duffy: The authors are indebted to all of the discussers for the interest they have shown in this paper and their remarks concerning it, all of which have added to the general value of the paper.

A number of questions have been asked and additional information requested, particularly by McKenzie, and it is felt that the best way to answer these questions is in the order given.

As stated in the paper, the authors feel that in any future station of the unit type, with split-phase generator protection, and with transformer-differential protection which includes the generator, no generator differential protection would be necessary. However, without the experience which has been obtained at Shipshaw in the reliability of the split-phase relaying, it would have been rather difficult, at the time the Shipshaw station was designed to eliminate the generator differential protection.

The authors are aware that split-phase protection in other forms had been used previous to the construction of Shipshaw, but the double-primary single-secondary type of current transformer was relatively new and untried, and other forms of this type of protection had not been found to be as sensitive.

In regard to the unbalances on the 36 phases, these were measured with normal full load on the generators and therefore it is felt that the designers and erectors of these units have done an excellent job. However, as pointed out previously, unbalances due to design and construction will be the limiting factor in the setting of the split-phase relay.

For cases where the generator differential or low-tension neutral relay operated at the same time as the split-phase relay, it should be noted that all of these relays are of the instantaneous or balanced-beam type and operate in one cycle or less. Therefore even though the split-phase relay may have operated first there is a matter of some five cycles before the fault is cleared by the circuit breaker which provides ample time for other instantaneous relays to operate.

The hot joint detected in the neutral ring bus was in the group bus to the neutral lead.

The time-current curves shown in Figure 7 are standard curves which may be found in the data obtainable from any of the relay manufacturers, or which may be obtained on particular relays by measurement.

As mentioned in the paper, the authors feel that the combination of back-up and overspeed relays have done an excellent job in detecting loss of field on a generator, even though not particularly designed to do this. It was not intended to imply that this combination was either the only or the best method of detecting this trouble.

It is felt that the 13.2-kv ground protection at Shipshaw is as sensitive as necessary and that the installation of special current transformers in the neutral connection for this protection alone would hardly be justified.

Lawton, in his discussion has outlined the reasoning behind the solidly grounded neutrals at Shipshaw. It might be added that experience has not shown any justification for more complicated grounding schemes.

The overspeed relays have maintained their settings very well, and while occasional operations of this protection may be obtained after a unit has been tripped by other protection, this is not a serious difficulty, and the sensitive setting is available when necessary for troubles such as loss of field. Maintenance and adjustment of these relays have presented no insurmountable difficulties during the years Shipshaw has been in operation. The governor solenoid operates through the valves, and there is no provision for high-speed closure of the gates.

The a-c overvoltage protection used at Shipshaw resets automatically. Experience with the gas-detector relay at Shipshaw does not bear out the arguments put forth by McKenzie. In a number of cases where relay operations have been obtained, the manhole covers have been checked for entrapped gas and very little or none was found. While it is not denied that gas could be trapped in any pockets formed by the windings, or core, or bushings, it would seem to be rather excessive to cover the top of the transformer with these relays, not to mention the expense involved. It should be emphasized that at Shipshaw reliance on these relays in their present location is considered to be justified completely. Lawton's discussion of this point probably has clarified somewhat the impression of an excessive number of incipient transformer faults.

One or two other questions have been raised by the other discussers, and should be mentioned.

Dupuis and Harker's question, concerning the use of 154-kv transmission voltage for just over two miles, has, we think, been answered by Lawton.

The authors do not feel that they are in a position to say whether split-phase protection could be applied to turbo-alternators. This would be a matter for the designers and manufacturers to decide, but it appears to be a matter worthy of some investigation by those who are interested. The point should be emphasized that relay protection is insurance, and that the expenditure on it should be a function of the value of the protected equipment. All other things being equal however, the cost becomes the main consideration. The connections at the Arvida terminal are basically a series of duplications of the connections shown in Figure 5 with proper bus segregation facilities. The protection at Arvida is primarily neutral overcurrent relaying as mentioned in the paper, but space does not permit any complete description of it here.

The apparently high incidence of faults on both transformers and generators at Shipshaw has been mentioned. It has been stated previously that all of the transformer troubles were of one type and the reason given. Similarly, the majority of the internal generator troubles have been on one generator. This unit, owing to wartime conditions, was installed at Shipshaw using reinsulated coils, after about two years of heavily loaded operation in another station. This was necessary in order to obtain power to meet wartime aluminum production demands. This unit is at present being completely rewound using new coils.

Rauth's reference to the co-operation of all the engineering groups involved is worthy of further emphasis. Without this co-operation, the construction of Shipshaw in record time, with the necessary attention to details, would have been impossible.

The Transient Behavior of the Two-Stage Rototrol Main Exciter Voltage Regulating System as Determined by Electrical Analogy

JAMES T. CARLETON
ASSOCIATE AIEE

THE excitation requirements of large turbogenerators necessitate an exciter which can develop several hundred kilowatts. On the other hand, the power available to control the exciter is often in the magnitude of milliwatts. This is especially true if static networks, utilizing nonlinear circuit elements are used to provide the reference standard.[1]

The 2-stage Rototrol main exciter provides the necessary excitation with a minimum of control power being required.[2]

In voltage-regulator systems it is desirable to maintain the output voltage of the generator within specified fixed limits through large variations of load and wide temperature ranges. Present voltage regulator practice requires that the voltage be maintained within one-half of one per cent of the desired value from zero to full load, and in the case of turbogenerators over a temperature range of from 20 to 80 degrees centigrade.

The self-energizing effect of the Rototrol series field can ideally supply full Rototrol excitation. However, due to slight changes in the generator field resistance, the Rototrol may be imperfectly adjusted. In this case the necessary Rototrol excitation must be supplied by a static network. It is then, that the high amplification of the 2-stage Rototrol is advantageous in maintaining voltage within the desired limits.

The introduction of the 2-stage Rototrol main exciter is of great advantage inasmuch as it provides the necessary excitation with sufficiently high system amplification to permit the use of a static network containing no batteries or electronic parts and using only one rotating d-c machine.

Furthermore, the fact that the Rototrol is series excited is of great importance when considering the effect of a short circuit on the generator. The transient field current produced by the short circuit[3] flowing through the series field increases the excitation and raises the internal voltage, thus adding greatly to the power system stability.

Description of the Regulating System

Figure 1 illustrates the voltage-regulating system under study.[2] The main unit is a 70,000-kva 3,600-rpm turbogenerator. The excitation is supplied by a 200-kw 2-stage Rototrol. The static network consists of a saturating reactor, the impedance of which is automatically compared with a capacitive reactance of constant value. As the generator voltage increases, the reactance of the saturating reactor decreases until at the regulated voltage, the reactances of both elements are equal. In this manner a reference point is obtained. The output of the static network is rectified by dry-type rectifiers and introduced into the control field of the Rototrol. The 2-stage Rototrol[4] itself consists of a 2-pole pilot exciter superimposed upon a 4-pole compound excited d-c machine. The control field is wound upon poles one and three. The armature is wound without equalizers. The control field flux produces an armature voltage, e_f, between brushes one and three. Had equalizers been placed on the armature, this voltage would be short circuited. However, in the case of the 2-stage Rototrol, this voltage produces a current i_f in windings connected between brushes one and three. Current, i_f, flows through a forcing winding which produces a flux in the 4-pole machine. This flux produces the voltage e_1 between brushes one, three and two, four. Voltage e_1 is applied to the generator field through a series field having sufficient turns to self-excite completely the Rototrol 4-pole machine when loaded with the generator field resistance. Hence it can be seen that the Rototrol is capable of supplying generator excitation due entirely to the flux produced by the series field.

A damping transformer, which is a mutual reactor providing derivative feedback, is placed across the output voltage of the Rototrol to stabilize the system.[1] The object of this investigation is to determine the optimum parameters to be used in the design of this transformer.

Stability of Regulator Systems

The Rototrol voltage regulator is a closed cycle regulating system of the proportional type. An error in output voltage, such as may be produced by a change in load, produces a proportional compensating change in excitation. Hence the generator output voltage is maintained within close limits at all operating conditions within the rating of the generator.

If the regulating circuit were opened at point X (see Figure 1), and a voltage e_0 were applied, it would be found that $e_0 = e_0Ae^{ja}$ where both A and a are func-

Figure 2. Two-stage Rototrol

(Upper left) schematic diagram, (lower left) equivalent circuit, (right) simplified equivalent circuit sponse characteristic, the classical method becomes cumbersome and impractical.

Transfer function plotting may be used to estimate transient behavior of the regulating system.[6]

Probably the most practical method of determining the response of a regulator system is by the use of an electrical analog. When large quantities of data for a considerable range of variables are required, the use of the electrical analog computer is definitely indicated.

By writing the differential equations that express the action of the various elements of the regulating system, one can by inspection or by circuit synthesis, devise electric circuits having exactly the same differential-integral equations as the original regulating system. These circuits form the analogy of the electromechanical regulating system and can be set up readily on the electrical analog computer for study. A disturbance $g(t)$ is introduced, and the transient behavior is measured with an oscilloscope. Parameters may be varied to determine the effect on the system and optimum proportions of components may be determined.

(Upper left) zero primary delay, (upper right) 18 per unit primary delay, (lower left) 0.30 per unit primary delay, (lower right) 0.36 per unit primary delay

Transient Behavior After Change in Reference as an Indication of Performance

In order to apply initial conditions to the system solution, a disturbance may be imposed upon the system. The type of disturbance most commonly encountered in voltage regulator systems of this type is a change in load. The disturbance may be considered to consist of two components: first, a change in internal voltage reference to compensate for the load flowing through the reactance of the machine, and second, an initial rate of change of generator voltage produced by increased inductance-reactance drop in the generator field.[1]

The ratio of the initial magnitudes of these components is determined by the nature of the load and the characteristics of the machine. However, since the total effect of the change in reference is predominant, for a general study of a large number of similar regulator systems that might be applied to water-wheel generators, turbogenerators, and synchronous condensers, a disturbance consisting of a change in reference only can be considered as representative.

Performance Criteria

In order to determine the optimum parameters for a regulating system, some measure of performance must be adopted. A criterion, to be applicable, must possess the following characteristics:

1. It must be a measure of the performance or transient behavior of the system and be of physical significance.
2. It must be calculable.
3. It must be measurable.

The criterion adopted for this study is as follows:[6]
Let e be the error voltage produced by unit change in reference voltage, then

$$T=\int_0^\infty e^2dt$$

if T is the criterion factor. By adjusting T to a minimum the error is compared to zero error by the method of least squares. T can be calculated by classical mathematical methods. If T is to be determined by electrical analog, an rms voltmeter may be used to read it directly. The actual regulator system T may be determined from oscillograms, by a recording voltmeter or by a watt-hour meter.

Should it be desirable to combine the effect of several components of disturbance each of which has been computed separately, the theorem of superposition may be utilized.

$$T^{1/2}=T_1^{1/2}+T_2^{1/2}\quad T^{1/2}\ldots\ldots\ldots\ldots$$

Analysis of System

Two-Stage Rototrol

Conventional Rototrol theory requires that the machine operate on the straight portion of the saturation curve. Therefore, the design of the 2-stage Rototrol is such that saturation is negligible throughout the operating range of the machine.

Figure 2 illustrates that, neglecting saturation and assuming balance between all four poles, the 2-stage Rototrol can be considered as three independent machines superimposed on one magnetic structure. Poles one and three, and poles two and four with associated brushes constitute two 2-pole machines. All the poles constitute a 4-pole machine.

An examination of machine constants reveals that current i_f' is approximately proportional to current i_f. A simplified equivalent circuit consisting of two compound wound d-c machines is obtained, the laws of which can be expressed by simple differential equations.

Damping Transformer with Primary Delay

Damping transformers in previous considerations[1,7] have been assumed to introduce a voltage into the control system proportional to the rate of change of the voltage that excites the transformer primary. This is true only if the time constant (L/R) of the primary is small. In that event, the primary current is proportional to the exciting voltage, producing in the secondary winding a voltage

MPe/R. Should the primary delay be appreciable, as is generally the case, the primary current is delayed and the induced secondary voltage $e' = tPe/1+TP$. Inclusion of the primary delay of each transformer increases the order of the system differential equation one degree, thus making a solution by classical mathematical methods more tedious.

OTHER COMPONENTS

Other components consist of the generator and the static network,[5] the analysis of which are amply described in the literature.

System Analog

The system analog is determined by inspection.[9] A form of inductive reasoning is employed. Blocks of previously used analogies are grouped together as suggested by the arrangement of the actual system. A trial analogy having been produced, its differential equation is written and compared with the differential equations of the actual system. If the equations of the analog circuits are identical, to those of the actual system, the analogy is acceptable.

In the analogy shown in Figure 1, R_2 C_2 represents the generator delay; R_0, L_0, C_0 represents the Rototrol delay; C_1, R_1 represents the self-energizing effect of the series field; and R_p, C_p represents the damping transformer with primary delay. Amplifiers supply system amplification A_1 A_2.

Conditions simulating change in reference and load are produced by the synchronous switch and battery combination shown.

Conclusion

In a previous study[1] it was observed that the generator voltage damping transformer, with negligible primary delay, is more effective than an exciter voltage damping transformer. However, a generator damping transformer is less desirable because rectifier and potential transformers are required. Therefore it was felt that an exciter voltage damping transformer having an appreciable primary delay might approach the performance of the generator damping transformer.

Figure 3 illustrates response to unit change in reference for several typical values of damping. Curve 2 having a mean square error of 0.085 T_2 second is the response obtained with optimum damping transformer parameters. It is interesting to note that the optimum value of primary delay is about 30 per cent of the generator, time constant.

The effect of delay in the damping transformer primary is illustrated in Figure 4. Mutual inductance is maintained constant at 4 per cent of the generator time constant, and L/R is varied.

The wide variations in performance indicate that primary delay is an important consideration in the design of a damping transformer.

Appendix I. Derivation of 2-Stage Rototrol Transfer Function

Consider the equivalent circuit of the 2 stage Rototrol illustrated in Figure 2. Let us demonstrate that i_f' is approximately proportional to i_f.

Writing the equation for voltage drops in the loop in which i_f flows we find:

$$e_f' = \left(R_f + pL_0 \frac{N_f''^2 + N_{0p}^2}{N_0^2}\right) i_f' - p\times\left(\frac{L_0 N_f''}{N_0}\right) i_0 - p\left(\frac{L_0 N_f' N_{0p}}{N_0^2}\right) i_f \qquad (1)$$

and

$$e_f' = K_f'\left(i_f - \frac{N_{0p}}{N_f'} i_f'\right) \qquad (2)$$

combining and assuming for the present that

$$i_o = \frac{i_f R_f}{K_o}(1+pT_f)$$

we find

$$\left(R_f + \frac{K_f' N_{0p}}{N_f'}\right)\left(1 + p\frac{\left(\frac{N_f'^2 + N_{0p}^2}{N_0^2}\right)}{R_f + K_f'\frac{N_{0p}}{N_f'}} L_0\right) i_f' = K_f'\left(1 + p\left(\frac{L_0 N_f' N_{0p}}{K_f' N_0^2} + \frac{L_0 N_f''(1+pT_f)}{K_f' K_0 N_0}\right)\right) i_f \qquad (3$$

Determining the numerical values of the time constants involved

$$\left(R_f + \frac{K_f' N_{0p}}{N_f'}\right)(1 + p1.24\times 10^{-3}) i_f = K_f'(1 + p(1.28 + 3.42(1+pT_j))10^{-3}) i_f \qquad (4)$$

It can be seen that first and second derivative terms are very small, (1 per cent of the control field delay) and may be neglected; therefore:

$$i_f' = \frac{K_f'}{R_f + \frac{K_f' N_{0p}}{N_f'}} = \frac{N_f'}{N_{0p}} i_f \text{(approximately)} \qquad (5)$$

Since i_f' is proportional to i_f the simplified equivalent circuit is valid where

$$N_0' = \frac{N_f' N_f''}{N_{0p}} \text{ and } b_0' = \frac{N_0'}{N_0}$$

Referring to the simplified equivalent circuit and writing the voltage drop in the control field we find

$$e_0 = i_0 R_0\left(1 + p\frac{L_0}{R_0}\right) - p\frac{L_0}{b_0'} i_f \qquad (6)$$

$$e_1 = K_0\left(i_0 - \frac{i_f}{b_f}\right) \qquad (7)$$

combining

$$e_0 = \frac{R_0}{K_0}(1+pT_0) e_f + \frac{i_f R_0}{b_0'} \qquad (8)$$

$$e_f = \frac{e_1 R_1}{K_f}(1+pT_f) - \frac{i_1 R_f}{b_f} \qquad (9)$$

$$e_1 = K_f\left(i_f + \frac{i_1}{b_f}\right) \qquad (10)$$

combining and letting

$$a_f = \frac{K_0}{b_0' R_f} \text{ and } a_1 = \frac{K_f}{b_f R_1'}$$

$$e_0 = \frac{R_0 R_f}{K_0 K_F}(1+a_f)\left(1 + p\frac{(T_0+T_f)}{1+a_f} + p^2\frac{T_0 T_f}{1+a_f}\right) e_1 - R_1 a_1\left(\frac{R_0 R_f}{K_0 K_f}\right)(1+a_f)\times\left(1 + p\frac{T_0}{1+a_f}\right) i_1 \qquad (11)$$

Appendix II. Nomenclature

n = Subscript denoting location of parameter
e_n = A voltage at location n
i_n = A current produced by e_n
R_n = A resistance through which current i_n flows
L_n = An inductance through which current i_n flows
$T_n = \frac{L_n}{R_n}$ = A time delay through which current i_n flows
$k_n = \frac{e(n+1)}{i_n}$ = A voltage generated due to a field through which current i_n flows
$a_n = \frac{k_n}{R_n}$
$b_n = \frac{N_R}{N_n'}$ = Ratio of turns of control field through which current i_n flows to turns of another field on the same machine
t_n = Time constant of damping transformer upon which e_n is imposed
T_{np} = Primary time constant of damping transformer upon which e_n is imposed

Table of Subscripts

n	Output Voltage of:	e_n
0	voltage regulator	e_0
1	pilot exciter	e_1
2	main exciter	e_2
3	generator measured at the secondary of regulator potential transformers	e_3
f	forcing voltage of 2-stage Rototrol	e_f
e	current in self-excited field of main exciter	i_e
s	current in shunt field of Rototrol	i_s
r	amplification of regulator	A

Detection of Overheated Transmission Line Joints by Means of a Bolometer

J. R. LESLIE
ASSOCIATE AIEE

J. R. WAIT
NONMEMBER AIEE

THE LOCATION of high-resistance transmission line joints on circuits long in service has been an almost routine procedure of many utilities for some time past. Considerable effort has been expended by The Hydro-Electric Power Commission of Ontario in making such measurements. Many of the circuits, of aluminum cable steel reinforced (ACSR) construction, are now over 25 years old. Bearing in mind the limited knowledge of techniques for joining aluminum conductors which existed at that time it is not surprising that some conductor joints began failing after a useful life of 25 or 30 years. The seriousness of such failures regarding danger to life, and interruption to service, is apparent.

The greatest offender has been the screw-type compression joint used on the early 110-kv circuits. This joint had an aluminum compression sleeve in two parts which threaded together. The screw portion in many cases was found to be the source of the high resistance. In some cases this portion must have become almost an open circuit, whereupon the line current passed through the steel sleeve. The resulting temperature rise was sufficient to soften the steel until the joint pulled apart. In other instances the current distribution was found to be nonuniform, a few strands carrying most of the current.

About 1939, the failures had reached sufficient proportions to warrant a full-scale investigation. Joint testers were constructed using a Wheatstone bridge circuit, the joints being compared with an adjacent portion of the cable of equal length. This testing was carried out by means of lineman's trolleys, with the line out of service but otherwise normal. Many miles of line were examined in this manner, during the years 1939 to 1941.

During the war, the development of infrared bolometers for heat detecting purposes progressed to a remarkable extent. The Germans had equipment of this nature which was capable of accurately tracking the course of a ship through the English Channel. The detectors, which were mounted on the Cliffs near Calais, France, picked up radiation from the ship's funnel.

The sensitivity of these devices, and their robustness was such that their application to the detection of overheated joints was considered practical. The authors describe such a device which was developed in the research division of The Hydro-Electric Power Commission during 1947 and 1948, following upon the prior description of a somewhat similar device by D. C. Niven, National Research Council, Ottawa, in a private communication.

With the infrared detector, joint temperatures can be measured with the line in normal service by merely setting up the detector's tripod to one side of the line and sighting the bolometer on the joint. This procedure takes less than five minutes time.

During the past two months, more than 300 transmission line joints have been checked. Present performance is such that, depending on terrain, and so forth, 25 or 30 joints may be measured on good days on a double circuit line. The temperature can be measured to ±5 degrees centigrade providing the joint is more than 10 degrees centigrade above ambient. The approximate joint resistance can be calculated.

Application of the device to heavy-current switch contacts and miscellaneous clamps also has been made. Of the first 12 switch contacts measured, one was found which was dissipating almost 200 watts on the contacts.

The demands on the apparatus for all this work are such that a 2-man crew is presently working full time with the apparatus.

Description of Instrument

The infrared detector or bolometer, is shown on its tripod in Figure 1. It consists of two parts—a parabolic mirror which collects the heat radiation from the joint, and a heat sensitive element mounted at the focus of the mirror. The sensitive element is a resistor with a high negative temperature coefficient. The change in resistance is a measure of the heat radiation falling on the mirror.

The parabolic mirror is made of glass, eight inches in diameter with a six-inch focal length. It is precision ground and has an aluminized front surface. The long wave infrared radiations given off by the joint do not pass through glass so that the polished aluminum must be on the front of the mirror.

The sensitive element is a Western Electric thermistor bolometer type *V651*,[1] developed by the Bell Telephone Laboratories. The active area (termed a flake by the manufacturer) is 2 millimeters by 0.2 millimeter, being about 10 microns thick. Thermistors are thermal resistors with a temperature coefficient of about −4 per cent per degree centigrade. The element is enclosed with a compensating element in a small housing with a rock-salt window through which the radiations pass without absorption.

The circuit is so arranged that the voltage across the thermistor is proportional to the resistance, and the sensitivity is given as 250 microvolts per microwatt incident radiation.

A front end view of the bolometer,

Paper 49-9, recommended by the AIEE transmission and distribution committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 12, 1948; made available for printing December 28, 1948.

J. R. Leslie and J. R. Wait are both with the research division of The Hydro-Electric Power Commission of Ontario, Toronto, Ont., Canada.

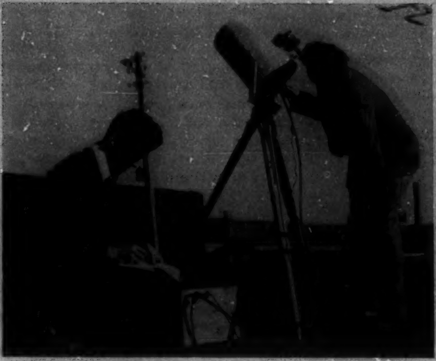

Figure 1. Bolometer in use

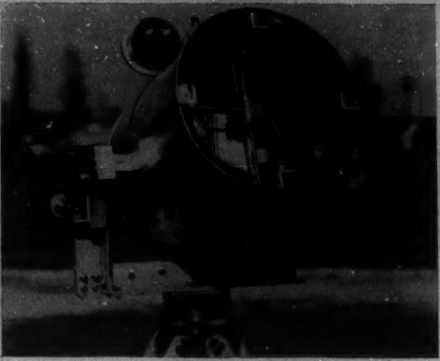

Figure 2. Bolometer, front end view

showing the general construction features, is shown in Figure 2.

In order to facilitate the amplification of the minute voltages set up by the bolometer, the incoming radiation is interrupted at a regular rate (15 cycles per second) by means of a rotating semicircular sector disk mounted in front of the element. The thermistor element is heated cyclicly at the disk frequency and cools by virtue of its small size each time the radiation is interrupted.

The disk is driven with an elastic band and pulley arrangement from a small motor mounted to one side of the mirror axis. The output of the bolometer is thus a 15-cycle square wave which can be amplified in a stable manner. The driving motor is a reed-synchronous type[2] having a speed variation of less than ±0.3 cycle per second. It is driven from a 6-volt motor cycle battery. The amplifier is tuned to the disk frequency so that it is insensitive to extraneous voltages. The box containing the amplifier and batteries is shown beside the tripod in Figure 1.

The use of a rotating sector disk has a further major advantage in that the chopping disk can be made of material (glass, mica, quartz) which is opaque to long wave radiations but passes the visible and near infrared waves. The latter are thus not modulated and produce only a d-c component (steady heating) which is not amplified by the tuned amplifier. The instrument thus becomes insensitive to visible light

It is shown below that although the total sky radiation may exceed that from a joint, it can be selectively filtered to a negligible value by the use of a glass or mica sector disk.

Thermal Properties of Joints

The total input power to a high-resistance joint consists of two parts, the I^2R power generated internally, and the incident radiation from the sun, called solar radiation.

The power losses are those due to radiation and convection.* Equating these two sets of power, we have

$$I^2R+P_s=P_r+P_c$$

Or

$$I^2R=P_r+P_c-P_s \qquad (1)$$

The bolometer enables only the first term (P_r) to be evaluated. The others must be calculated or determined experimentally. We shall deal with each separately.

Radiation Losses (P_r)

The radiated power from a cylindrical conductor of length, L, diameter D in centimeters has been given[3] as

$$P_r=18.55\times10^{-12}LDE(T_2^4-T_1^4)\text{ watts} \qquad (2)$$

where

E = the emissivity of the surface
T_2 = the conductor temperature, degrees absolute
T_1 = the ambient temperature, degrees absolute

The emissivity of a body is defined as the ratio of the power radiated per unit area of the material to that radiated by unit area of a perfectly black body at the same temperature.[4] The emissivity of bright aluminum is given as 0.1 or less. A light layer of soot increases E to as much as 0.8. Hence eight times as much power is radiated from a soot-covered joint at temperature T as from a new joint at temperature T. On the basis of an investigation by Hutchings and Tuck,[5] lines more than two years old should have E values of 0.5 or higher. Obviously this value will depend on the presence of factories, trains and so forth, close to the line. This uncertainty in the value to be ascribed to E may be one of the largest sources of error in calculating the resistance from the temperature.

Using the following typical values in equation 2, we have: $T_1=22$ degrees centigrade = 295 degrees Kelvin; $D=1.8$ inches = 4.6 cm.; $T_2=50$ degrees centigrade = 323 degrees Kelvin; $E=0.5$; and $L=24$ inches = 61 centimeters. Therefore $P_r=9.2$ watts.

Assuming spherical radiation, the intensity in watts per square foot at a distance of say 70 feet is easily calculated. The power finally incident on the thermistor works out to 38 microwatts. For a sensitivity of 250 microvolts per microwatt, we have E_r = 9.6 millivolts, which is easily measured.

Convection Losses (P_c)

In still air the joint is cooled not only by radiation but by natural convection. The air film adjacent to the joint surface becomes heated by conduction and hence rises. These gravity air currents dissipate a considerable portion of the power input to the joint.

Forced convection is caused by a wind which displaces this air film in a horizontal direction causing further cooling. For a joint at 60 degrees centigrade in a two miles-per-hour wind the total forced convection heat loss is about four times the radiated power loss.

---

* Conduction losses were found to be negligible.

Curves of natural convection and forced convection losses for various temperatures and wind velocities are calculated for the joint from both theoretical[4] and empirical[5] data.

From the foregoing data it is possible to calculate the total power dissipation (P_r+P_c). If the forced convection is great enough, then it can be reasonably assumed that the natural convection is completely replaced. However for low-wind velocities of the order of 0.5 mile per hour the calculated forced invections loss is of the same order of magnitude as the natural convection. Hence the assumption adopted is to evaluate the combined convection loss by taking the square root of the sum of the squares of both losses. In this way the natural convection is conceived of as a vertical current of air whereas the forced convection is a horizontal current of air.

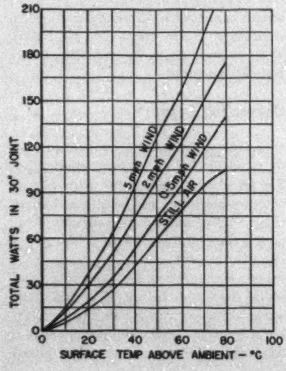
For a given temperature, the total power being lost from the joint is the sum of the combined convection loss and the radiation loss. For example, when the joint temperature is 60 degrees centigrade the power radiated is $P_r = 14$ watts for an emissivity of 0.5 with an ambient of 22 degrees centigrade. If the wind is two miles per hour, the forced convection loss is 52 watts. The natural convection is calculated as 25 watts. The power loss or total wattage dissipation in the joint will be equal to

$$P_r+P_c=14+(52^2+25^2)^{1/2}=72 \text{ watts}$$

In this way a set of curves of total wattage (P_r+P_c) is plotted versus temperature rise for various wind velocities. See Figure 3.

Figure 3. Power dissipation and temperature rise for a joint

Joint diameter 1.8 inches, emissivity 0.5



Using an actual high-resistance joint with currents up to 400 amperes, the calculated wattage dissipation curves were checked to about 10 per cent, which is within the experimental error in measuring wind velocity and other factors.

Solar Heating (P_s)

As mentioned, the power input to a joint is equal to the sum of the current heating plus the solar heating.

The intensity of solar radiation at the earth's surface neglecting atmospheric absorption is given[6] as 137 milliwatts per square centimeter at right angles to the sun's rays.

However, actual measurements on the earth's surface during a clear day indicate values of the order of 100 milliwatts.[7]

Hence the wattage incident on the joint will be the intensity of radiation multiplied by the projected area. The absorption coefficient (= emissivity) will be taken as equal to 0.5. If the joint diameter is 1.8 inches (4.6 centimeters) and the length is 30 inches (76 centimeters), then the total wattage absorbed by the joint is given by

$$P_s=0.10\times0.5\times4.6\times76=18 \text{ watts}$$

Sky Radiation

The thermistor element "sees" the back of the sector disk on one-half cycle of the disk's rotation and the joint plus a fringe of sky on the other half cycle. The bolometer measures the difference between the effective temperatures in each case.

To reduce as far as possible the effect of the extraneous sky radiation it is desirable to make the effective sky temperature equal to the effective disk temperature. Then with the sky reading equal to zero the bolometer reading will be proportional to the difference of the joint and disk temperatures.

With a clear blue sky, where there is little direct infrared radiation, the use of a polished copper disk was found to result in a low sky reading. The effective temperature of a polished copper disk is very low due to its low emissivity. This same disk, however, gave an excessive reading on clouds or haze.

With a cloudy sky, glass, mica, and lithium fluoride disks were used which all gave low readings on a uniform grey sky whether dark or light. The effective temperature of a cloud is lowered with these disks because part of the radiation produces a d-c output only, which does not contribute to the reading.

Although the complete explanation is more complicated than this, the experimental data show the same sensitivities for a copper disk and a blue sky as with a mica disk and a cloudy sky. The calibration curves for the infrared radiation are not affected by changing disks because both disks interrupt such rays.

Calibration

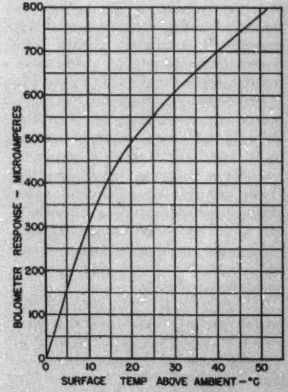
Having been provided with a curve, Figure 3, showing temperature rise above ambient for any wattage loss in the joint, it is only necessary to measure the temperature with the bolometer to enable I^2R, hence R, to be found. The bolometer calibration curve was obtained experimentally.

Because a high-resistance joint was not available early in the investigation, an artificial "hot" joint was constructed using a standard aluminum compression sleeve with short lengths of conductor (605,000 circular mils) in which the steel sleeve was replaced with a length of glass-insulated nichrome resistance wire. The ends of this wire were brought out of the sleeve through the holes normally used to insert No-oxid grease. The surface temperature of the sleeve and the bolometer reading were then obtained for different heater powers.

Figure 4 shows the response of the bolometer to this joint when soot covered, for various temperatures. Because the image

Figure 4. Bolometer response

Valid to ±5 degrees centigrade for distances from 50 to 65 feet. Conductor joint 30×1.8 inches. Surface color—dark grey



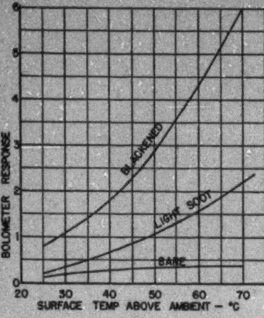


Figure 5. Effect of surface condition

of the joint at the focus is larger than the area of the thermistor flake for this particular joint, the reading is independent of distance over the limits 35 to 70 feet.

Figure 5 shows the effect on the response of varying the surface finish or emissivity. All the older joints in Southern Ontario would be of the blackened type, at least on their under surface. In northern regions this may not be the case. An individual calibration is planned for each typical case.

It was decided also that calibration curves would be desirable for each of the different types of joints, parallel clamps and so forth. These were simply obtained by heating the latter with a blow torch, then reading the bolometer over a half-hour period as it cooled, the temperature being measured with a thermocouple.

After the first high-resistance joint was found, and cut out of the line, it became possible to obtain a direct check on the radiation and convection loss calculations. The joint, of 2,000 microhms resistance, was set up in the laboratory and typical currents were passed through it. The effect of wind cooling on surface temperature was obtained directly using a large fan. The curves obtained theoretically in Figure 3 were checked and found to be substantially correct.

Field Tests

After many preliminary tests, routine measurements were started about August 1, 1948. Readings can be obtained only on days with little or no wind, as the theoretical considerations show that the cooling in a ten miles per hour or higher wind becomes many times the radiation loss. Thus very few joints would run hot on these days. In addition, the accuracy with which the total watts loss can be found is very low with high winds. Of course the bolometer measures at all times the actual temperature irrespective of wind.

Table I. Test Results on First Overheated Joints

Circuit	Current	Wind	Sun	Estimated Temperature Rise, Degrees Centigrade	Calculated Resistance, Microhms
1. *Y3T*	100	0	Bright	35	4000
2. *Y3T*	100	0	Obscured	30	3000
3. *B2 HS*	100	5	Bright	35	3000

First tests were performed on two double circuit lines ($5^1/_2$ and $6^3/_4$ miles long) both having screw-type compression joints, 110-kv construction, and 477,000 circular-mil aluminum cable, steel-reinforced. These lines were placed in service in 1924–25. Three joints (out of 30) showed signs of overheating. The data are given in Table I.

These joints were subsequently cut out and tested in the laboratory. Joint number 1 alone was very high in resistance, measuring 2,000 microhms compared to a normal value of 45 microhms. Joints 2 and 3 were 38 and 96 microhms respectively. The latter two were then placed under tension and again measured. Joint 3 was unstable and had then increased to 280 microhms, joint 2 did not change. A current of 200 amperes was then passed through these two joints while still under tension. Joint number 3 had increased to over 300 microhms after three days.

Measurements at a much earlier date (1940) on a similar high resistance joint showed it to have a resistance inversely proportional to the current. The voltage drop across this joint for heavy currents of different values was constant.

It was also noted that joint number 3 had been made using a sleeve larger in size than the others (probably a 795,000 circular-mil sleeve). Compressing it originally over the 605,000 circular-mil conductor had cracked the aluminium in two places.

A double circuit line, 26 years old running from Queenston, G.S., to Hamilton was then tested. This line of 605,000 circular-mil aluminum cable, steel reinforced, 40 miles long had 310 screw-type joints. They were tested by a 2-man crew in less than two weeks time. Eight overheated joints were found, the hottest running at about 50 degrees centigrade over ambient with a line current of the order of 280 amperes. Table II lists these joints together with their estimated temperature rise, the wind velocity, type of sky, and line current. The final column in Table II shows the results of resistance measurements on seven of the eight joints. The line was taken out of service and the resistance obtained from a millivoltmeter reading using 100 amperes direct current. The first four resistances were measured by lowering the conductor to the ground without disturbing the joint. They measure five to ten times normal. Two of the remainder, which do not measure high in resistance, were measured using a lineman's cable seat. The trolley in passing over the joints

may have altered their resistance. The third was partially lowered, then reached by means of a ladder.

The authors concluded from all these tests that the resistance of a faulty joint is an extremely variable quantity. Removing or increasing the tension or handling of any nature could cause the resistance to vary in an unpredictable manner. This is natural considering that the resistance must lie in thin films of oxide or contamination, these films being easily broken by removing the strains in the material.

Using the value of emissivity and solar heating quoted before, these joints were all estimated to have over 1,000 microhms resistance so that the theoretical curves relating watts loss to temperature rise (Figure 3) may be in error. Further experience will enable more accurate curves to be drawn. The arbitrarily chosen value of 0.5 for the emissivity may be high. The effect of solar heating on temperature rise has not been checked experimentally.

Tests on Disconnect Switches

Twelve 13.2-kv disconnect switches were tested at Leaside transformer station. These switches connect four 25,000-kva synchronous condensers to the 220-kv system of The Hydro-Electric Power Commission of Ontario.

They were carrying 1,300 amperes at the time of test.

The bolometer was set up about 50 feet from the switching structure and sighted on the contacts. One switch was found to be running at a temperature estimated to be 65 degrees centigrade. The remainder were at less than 30 degrees centigrade. The overheated switch was taken out of service at the earliest opportunity (and found to be still warm one-half hour after the interruption). From the measured resistance it must have been dissipating about 200 watts across the contact fingers.

Conclusion

Temperature measurements on conductor joints and switch contacts are believed to be rapidly and simply made with the infrared detector described. The accuracy obtained is thought to be better than five degrees centigrade.

The prediction of the power dissipation or resistance of the joint or switch is a more difficult matter. In fact there is strong evidence to support the view that these high resistances are an extremely variable quantity, and that temperature rise may be the most reliable index of a joint's condition.

Further studies of the influence of wind cooling, solar heating and the condition of the surface on temperature rise are indicated.

Application of the bolometer to temperature measurements on rotating parts may be possible.

Discussion

N. L. Kusters (National Research Council, Ottawa, Canada): A project similar to that described by the authors of this paper has been in progress at the Canadian National Research Council since 1946.

Early in our investigation we chose to use a-c amplification following the infra-red sensitive bridge, because of the difficulty of achieving high stability in a d-c amplifier for portable use. Having made this decision, an investigation was made of systems using: a circuit-breaker type of chopper to interrupt the output of a d-c volometer bridge; a radiation chopper in connection with a d-c bolometer bridge as used by the authors of this paper; and an a-c bolometer bridge.

It was found that the circuit-breaker type of chopper was satisfactory for use only with low-impedance bolometers, such as the German antimony bolometer, due to capacitive pickup difficulties.

The radiation chopper system, as used by the authors, was tested using the Western Electric *V651* bolometer and a low-impedance platinum bolometer from Baird Associates. Various forms of chopping disks, concentric tubes, and so forth, were used, but early in 1947 this system was abandoned for the following reasons:

1. Difficulty was experienced in maintaining the back of the chopper, which is the reference level for measurement, at a constant temperature.
2. Chopped systems do not provide indication of both hotter and colder bodies as readily as the a-c bridge.
3. As pointed out by P. Moon in 1935, there is no conversion loss using a bolometer in an a-c bridge. With a radiation chopper or circuit interrupter there is about a 40 per cent loss.
4. The use of a motor-driven disk, as used in the authors' instrument and which must be changed for different sky backgrounds, was not considered suitable in a rugged, portable instrument.

The Western Electric bolometer was chosen as best suited for use with an a-c bridge, and a bridge supply frequency of 1,000 cycles was selected as a compromise between the shunting of the bolometer element by stray capacities at higher frequencies, and the use of large electrical components in the amplifier at lower frequencies.

The use of 1,000 cycles instead of the 15-cycle chopper permitted the use of three small plug-in units containing all the electronic circuitry including nine subminiature tubes. The battery drain is very small, so all batteries are mounted within the case of the instrument.

The theoretical maximum sensitivity of the National Research Council instrument is 0.18 microwatt for full-scale deflection. The noise level of about one microvolt permits a minimum detectible signal of the order of 0.01 microwatt.

The authors are to be complimented on the success they have achieved in the quantitative estimation of the temperature and the resistance of the joint. We believe, however, that it is more practical to limit the use of the instrument to an indication of the temperature difference between the joint and the conductor. The resistance of a faulty joint varies widely, as pointed out by the authors; also, the emissivity of the surface examined varies from about 0.04 for polished aluminum or copper, to 0.92 for glazed porcelain. These factors, together with the necessity for reference to a multitude of curves for various wind velocities, limit its practicability as a field instrument. Consequently, our instrument is designed to give the temperature of the joint relative to that of the conductor itself, and emphasis has been placed on portability and simplicity of operation and maintenance.

A number of field tests have been carried out since early 1947, in co-operation with the Shawinigan Water and Power Company. In these tests, clamps, compression joints, twisted joints, and wave traps were checked, with considerable success.

1. Theory of A-C Bolometer, P. Moon. *Journal*, Franklin Institute (Philadelphia Pa.), January 1935.

A. S. Runciman (The Shawinigan Water and Power Company, Montreal, Canada): This paper gives an excellent idea of what may be accomplished by using the bolometer method for locating overheated joints or fittings on transmission lines, either high or low voltage. The authors have done work which should be of considerable assistance to others later. They point out the cooling effect of even a light breeze; a wind 10 miles per hour prohibits satisfactory use.

It has been observed on the Shawinigan system that the background should be uniform and preferably blue sky as the authors indicate.

One point on which we would like to question the authors is the feasiblity of using the apparatus in cold weather. Nothing is mentioned in the paper about the circuits used; therefore, it is not possible to estimate the effect of changing temperature on the balance and indicating equipment.

Field tests carried out on the Shawinigan Company's system in 1947, located a defective screw-type aluminum compression joint on the first trial. It was not possible with the early apparatus to obtain quantitative measurements. The authors have gone a long way in developing apparatus which can determine within reasonable limits actual temperatures.

This paper, no doubt, will bring to mind many other uses; one very simple and much needed application might be entirely outside of the power field, that of indicating heat leak spots on buildings.

The National Research Council has developed similar apparatus using no mechanical chopper but a 1,000-cycle amplifier. The sighting system of their apparatus is an optical arrangement by which the observer sees the object and the instrument reading, in the one eye piece.

A recent field trial of this apparatus, located an overheated wave trap in a 220-kv line. The wave trap was radiating approximately 100 watts. This loss was compared with a 100-watt yard lighting lamp at approximately the same distance and equivalent indication obtained.

The authors are to be highly commended for establishing the practicability of using bolometers on field work.

Leonard M. Olmsted (Duquesne Light Company, Pittsburgh, Pa.): The authors have presented an interesting report on a unique method for determining the adequacy of transmission line joints with the lines remaining in service. It seems to me, however, that a slight change in point of view would eliminate their difficulty with several variables entering into determination of the joint resistance.

Fundamentally a joint should be looked upon merely as a means of joining line conductors. As such, its requirements can be defined as matching the characteristics of the conductor with respect to mechanical strength, current capability, and permanency. From this point of view, it seems entirely justifiable to measure the adequacy of the joint in terms of its performance relative to that of the conductors. If practically simultaneous measurements were taken with the bolometer of the temperature of the joint and the temperature of the conductor at a suitable distance from the joint, then any difference could be determined directly. It is entirely reasonable to assume that such variables as sun radiation, air movement, surface conditions, and atmospheric temperature would remain substantially the same during this comparative test and that any difference in the effect of these factors upon the temperature of the joint or the conductor would be so slight as to be considered negligible.

Joint resistance is, of course, a convenient basis of comparison for laboratory tests and manufacturing control. It is my opinion that the proper limits for joint resistance should be established by test of joints which have been proved satisfactory under field operating conditions, using the bolometer or other devices to ascertain the field condition. It does not appear necessary to measure the joint resistance in the field, and I strongly urge that the complications besetting such determinations be avoided by using the bolometer solely for comparative measurements.

Engineers of the Bonneville Power Administration (Portland, Oreg.): Application of the bolometer method to measuring heat radiation from conductor joints appears to us unique and to offer considerable possibilities in the utility field.

In reading the paper we note that no mention is made of the method of determining wind velocities, which have a most noticeable effect on convection losses (P_c). In making conductor vibration studies on the Bonneville Power Administration system, it is found that wind velocities vary considerably from the ground to the conductor level. For this reason it would seem desirable that an anemometer be installed near the conductor level in order to obtain more accurate wind velocities. The paper states that heat measurements are made in a short interval of time indicating that wind velocity measurements probably are not made at the conductor level. If the anemometer method is used to determine wind velocities for convection losses, it would obviously require considerably more time in making tests of each joint than that shown by the authors.

Since all of the lines of the Bonneville Power Administration system are less than ten years old and, also, since the approved-type compression joints are used on all connections, we have not experienced to date any unusual failures due to overheating of joints. Even though properly made compression joints are used on all of the transmission lines being designed at the preset time, there still is the apparent need for an occasional check for heating of joints, switch contacts, and other contact-making surfaces.

In our experience of checking overheating of contacts in our substations, we use what is probably the simple, universal method. Our low-voltage substation disconnecting switches are checked for overheating by means of a wax candle on a switch stick. If the switch is hot enough to melt the wax, the switch is taken out of service for maintenance at the earliest opportunity. This simple test is made at regular intervals by the substation operators, and seems to be quite satisfactory. As for the 115-kv and 230-kv disconnecting switches, they are generally not loaded to the point where heating is a problem, and periodic maintenance seems to keep them in satisfactory condition.

J. R. Leslie and J. R. Wait: Replying first to Kusters, it is true that the bolometer we have described gives no indication as to whether the body sighted on is hotter or colder than ambient temperature. However, in practice this has caused little difficulty. In the few questionable cases to date, the addition of a small amount of radiation such as from a match, or the hand held in front of the mirror indicates the proper polarity.

The authors are in favor of the use of a sector disk because of its ability to filter out a great part of the radiation from clouds. This radiation is thought to be scattered solar radiation of shorter wavelength than that from a joint. It is very difficult to sight on the conductor alone, therefore background radiation should be low.

The suggestion by Olmsted and Kusters that joint and cable temperatures be compared directly has been made. This procedure is sufficient only to show that no temperature difference exists. If a temperature difference is indicated, and it usually is, its significance must be determined. What is required is the maximum temperature which the joint can attain in the absence of wind. The curves relating forced convection loss to temperature rise, Figure 3, must therefore be used. With these curves, the temperature rise under the worst conditions may be estimated. It is apparent that with sufficiently strong winds, all temperature rises would be reduced to negligible values. With the use of the curves then, what is obtained is a number, the resistance, corresponding to the temperature rise without wind cooling.

In the practical use of the bolometer to date, none of the conductors has experienced a measurable temperature rise other than that expected due to solar heating. This is because of the rather low currents in the older circuits examined. Thus, all conductors have been "cold" as far as the bolometer is concerned. It is interesting to note that two idle conductors of different size, exposed to the sun's radiation, will not experience the same temperature rise.

Runciman inquired as to cold weather operation. The bolometer has not been in use during the winter months but should operate without difficulty. Temperature rise above that of the sector disk is measured at all times.

Replying to comments by Bonneville engineers, the present practice in determining wind velocity is to climb the tower to a height of about 20 feet and with an anemometer obtain the average velocity during a 1-minute interval. Errors due to turbulence around the tower may be appreciable, and a better procedure would consist of raising the anemometer on a long pole to conductor height. This idea was abandoned for reasons of safety.

A further uncertainty is caused by wind direction, convection loss in this case being difficult to obtain. Procedure now used is to list all of the joints giving evidence of overheating and to re-examine these under conditions of low or zero wind and with high load currents, when possible. This has not proved difficult to do as the number of overheated joints is small.

The need for an occasional check on the heating of joints, disconnects, and bushings has been proved to us by the frequency of requests for such measurements.

The interest shown by the discussors is appreciated. It is hoped that additional field data will be available in a few months time.

Comparison of Long-Time and Short-Time Analog Computers

VICTOR PASCHKIS
NONMEMBER AIEE

THE USE OF electrical analog computers for the solution of transient heat flow problems had been realized first by C. L. Beuken.[1] In the United States the early published accounts describe an apparatus erected at Columbia University,[2,3] now known as the Heat and Mass Flow Analyzer, and henceforth referred to as HMFA. Various less extensive versions of the Columbia University apparatus have been constructed elsewhere,[4,5] and a still further development has modified the technique of execution.[6,7,8]

These later modifications offer certain advantages but necessarily entail certain disadvantages. In view of the increasing significance of the analog computers, it is important to weigh the advantages and drawbacks of the various modes of execution of the analogy idea; such a comparison is the purpose of this paper. Of course such computers can be applied to a large variety of problems. This paper deals exclusively with their application to heat flow problems.

Basically, the analog computers for transient heat flow problems are resistance-capacitance networks with suitable power supply systems and measuring devices. In Figure 1 an example is shown of the so-called "1-dimensional network" used for the calculation of 1-dimensional heat flow problems. Figure 2 is an example of a 2-dimensional network.

Figure 3 is a plan view of the heat and mass flow analyzer laboratory which covers a floor space of 530 square feet. The circuit elements of the apparatus comprise 120 resistor sections and some 720 individual capacitors. One pole of each of the latter is permanently grounded. The total capacitance is approximately 3,000 microfarads. The units are so arranged that almost any combinations can be assembled readily. To that end, resistor sections, each consisting of four decades, are mounted on 20 boards—six sections on one board. From four to eight capacitor units are placed in one tray and a total of 108 trays are placed in four frames. The trays are equipped with jacks which are connected to the various capacitors of each tray. In each capacitor frame there are also four busboards, each containing 12 busses. For each experiment the capacitors required for any one section are connected by flexible leads to the busboards.

The ends of the busses as well as the two ends of each resistor section are connected in turn to the "main panel" shown in Figure 5, on which the network connections are made. The latter consists of five boards: one for the outlets of the resistors, two for the outlets of the ends of the capacitor buses, and, finally, two "grounding devices" which make a rapid discharge of the capacitors possible after each experiment. On the main panel, the circuit representing the body is prepared.

Overhead wires lead to an instrument panel on which the necessary recording instruments, power supplies, and similar equipment are mounted. Figure 4 shows part of the resistor and capacitor frames.

The various modifications of the Columbia University apparatus referred to before differ with regard to the time constant of the individual element. In carrying out electrical experiments it is not necessary that they last as long as the corresponding heat occurrence. A time scale may be applied, expressed by the "Time Ratio" (*TR*). In calculating a circuit to represent a thermal phenomenon the time ratio applied is given by

$$TR = \frac{\tau_E}{\tau_H} = \alpha CR \qquad (1)$$

Here τ_E and τ_H denote the "electrical" and the "heat" time respectively. C is the capacity (microfarad per cubic foot), R is the resistivity (megohm times feet) used in calculating the network, and α is the thermal diffusivity of the body subjected to heat flow. The dimensions megohm per foot and microfarad per cubic foot appear unusual and require explanation. In calculating the circuit to represent a body, the latter is being considered as being composed of a number of discrete parts or sections. Each section is represented by one "lump" in the network.

The electrical values for these lumps are calculated on the basis of the geometric dimensions of the section represented; the capacitance is proportional to the volume and the resistance to the ratio thickness per cross sectional area. Thus, a high value of time ratio, *TR*, indicates that a certain thermal phenomenon is represented by a longer lasting electrical experiment than with a small value of *TR*. The *HMFA* at Columbia University is designed so that, for any given process, a time ratio of much greater order of magnitude can be used than is possible with the later modifications of the analogy method. This, of course, means that the *HMFA* comprises a much larger total capacitance and resistance than the modification; in fact, this difference in capacitance and resistance is the distinguishing factor.

Significance of Time Constant

In connection with analog computers, the time constant *RC* (capacitance times resistance) has to be considered from various aspects, namely: instrumentation,

---

Paper 49-13, recommended by the AIEE computing devices committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 30–February 4, 1949. Manuscript submitted November 16, 1948; made available for printing January 17, 1949.

VICTOR PASCHKIS is technical director of the heat and mass flow analyzer laboratory of the department of mechanical engineering, Columbia University, New York, N. Y.

Figure 1. Equivalent network circuit for 1-dimensional problem

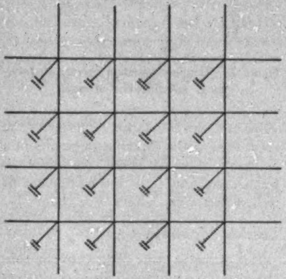

Figure 2. Equivalent network circuit for 2-dimensional flow

manipulation, leakage, and cost of equipment.

To put the problem into proper setting, it should be understood that runs on the *HMFA* last from several minutes to several hours, whereas on "short time apparatus" the phenomenon occurs in a fraction of a second. In way of example, take the case where an experiment on "short time apparatus" lasts 0.1 second; then the former needs 3,000 times the amount of *RC* used in the latter, and this is in no way extreme. An intermediate design uses time constants of such magnitude that the individual experiments last from fractions of a second up to several seconds.

INSTRUMENTATION

In order to register the readings—voltage and current—special instrumentation is required. The *HMFA* comprises modern fast-recording instruments, printing every two seconds. It is hoped that eventually even faster recording instruments will become available.

For many experiments with slow changes, the instruments can be either multiple-point recorders or slower recording instruments. In one run it usually is possible to record a number of variables—voltages at different points or voltage and current, and so on.

For the "short-time apparatus" the only possible recording device is the oscillograph. However, operation of an oscillograph requires more power than is available in short-time apparatus. A record can be obtained by filming the readings on an oscilloscope, showing the transient together with a time scale. Because of the high cost of the oscillograph, the short-time apparatus has been built to date with oscilloscopes for indicating measurements. For the "intermediate-time apparatus," pen-type recorders may be used, recording occurrences as short as 0.5 second. If, as is mostly the case, recordings at several points are required, a separate instrument for each point must be provided. Of course, sometimes several pens are combined in one instrument utilizing different parts of the total width of the paper. The width of any one record is limited compared with the records used for long-time experiments.

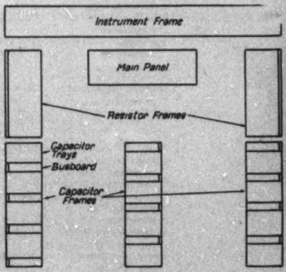
The accuracy of measurement on an oscilloscope is limited to probably 2 to 5 per cent of the full-scale value or less, and can be improved to 1 per cent only with extreme care; whereas the accuracy of the recording instruments used in long-time experiments is 1/5 to 1/3 per cent. It may appear, at first, as if an accuracy of 5 per cent might suffice, particularly in view of only an approximate knowledge of the thermal properties. Frequently, however, measurements at the lower end of the scale are required, where the percentage of error increases very markedly beyond that incurred with full scale.

This increase in error is proportional to the scale reading in recording instruments; it generally is more than proportional on oscilloscopes because of the lack of linearity in the tubes.

MANIPULATION

Under this heading several operations are covered. First, consider the boundary conditions. In some instances the impressed voltage may change with time, representing a time-dependent change of ambient temperature. Such a change can be represented on the *HMFA* in steps or continuously by manual control, because the experiment is slow enough to permit such operation. On intermediate-time apparatus and short-time apparatus, an input circuit is required to produce the desired voltage function. Hence, programs with frequently changing input conditions are solved more readily on the *HMFA* than on the two other types of equipment.

Figure 3. Plan view of heat and mass flow analyzer laboratory



One of the very important objects of the electrical analogy work is the solution of problems with variable parameters, mainly with resistance and capacitance varying with voltage. This voltage dependence represents a temperature dependence of thermal conductivity and specific heat respectively. Of course the form and degree of dependence may be different for various materials.

In the case of short-time and intermediate-time apparatus, it is possible to obtain such variable parameters by designing electronic circuits to replace resistance and capacitance in the network, and to incorporate in the design the desired voltage dependence. However, different circuits have to be used for different degrees and modes of voltage dependence. For intermediate-time apparatus the use of cam-driven equipment is conceivable for changing parameters through relays.

On the *HMFA* changes of resistance and/or capacitance can be effected in steps. At those points in the network where "varying properties" prevail, the voltage is observed and, at certain predicted values, the resistances and capacitance of that section are changed manually by operating appropriate switches or relays. This method of operation is possible because the time

Figure 4. Resistor and capacitor frame, heat and mass flow analyzer laboratory

lapse between consecutive steps is sufficiently long to permit reading of instruments, and so forth.

Still another topic under the general heading of manipulation concerns problems where certain physical happenings are to be represented within the range of a heat flow problem. Consider, for example, a problem where two materials are alternately in and out of thermal contact. If this alternation is at regular intervals, depending on time only, no difficulty is encountered in using short- or medium-type apparatus. But if the intervals are irregular or depend on observation during the run of an experiment, only the long-time computer is feasible.

LEAKAGE

The accuracy of operation of analog computers hinges on keeping three sources of error small: errors because of leakage, lumping, and errors in instruments. The latter have been discussed in the section on instrumentation. The errors through lumping depend on the number of sections or lumps; if their number is kept constant, the error at any relative time (time from the start of experiment to a given instant, divided by total length of experiment) is independent of the length of the experiment.

The errors through leakage can be understood from Figure 6, which refers to a 1-dimensional network. Because the capacitors are not perfect, but have a leakage resistance, the equivalent circuit contains a shunt resistor for every capacitor. Moreover, in the physical arrangement of capacitances and resistances it is inevitable that leakage paths exist between the input point and various points in the circuit. Instead of the simple circuit, shown in Figure 1, the more complex circuit, Figure 6, must be used to represent the actual analog computer. The error incurred will vary depending on the relative size of the "useful" and the "leakage" resistances.

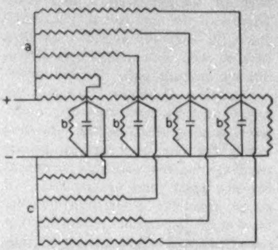


Figure 6. Equivalent network including leakage

a. Leakage from power supply to network
b. Leakage of capacitors
c. Leakage from network to ground

Figure 5. Main panel, heat and mass flow analyzer laboratory

Now, from the viewpoint of leakage, short-time and intermediate-time setups offer two advantages. First, the *RC* value is proportional to the length of the experiment. Hence, for short experiments it is possible to work with small capacitances. At least in the case of short-time computers and possibly even in the case of intermediate-time computers, the capacitances can be made so small that extremely high-quality capacitors, mica or polystyrene, become economically feasible. Secondly, the low value of useful resistance, required for the short time of the experiment, results in a favorable ratio of useful resistance to leakage resistance for the equipment as well as for the capacitors.

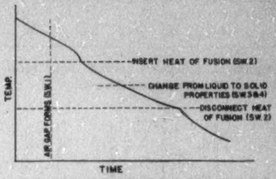

Figure 7. Time–temperature curve near interface; solidification of metal

COST OF EQUIPMENT

It is of course quite difficult to compare the cost of the various kinds of computers in a comprehensive way, because there is an infinite variety of possible designs for each of the three types.

The following general statements may be helpful. The cost of an analog computer comprises three groups of items: the input arrangement, the circuit elements (resistors and capacitors), and the measuring and recording devices. The input arrangement, if flexibility is desired, is more expensive for short- and intermediate-time computers than for long-time computers. The circuit elements, for work with constant parameters, are less expensive for short-time and medium-time computers than for long-time computers. If the parameters are not constant the conditions, generally, will be reversed and the long-time computer will be in the lead. The measuring equipment for equal performance (that is,

Table I. Analogy Equipment

Item		Short-Time	Medium-Time	Long-Time
Instrumentation	Type	Oscilloscope or oscillograph	Single-point high-speed recorders	Recording instruments
	Accuracy	Low	Fair	High
Manipulation	Constant boundary conditions	No difference between types		
	Varying boundary conditions	Special input circuit for every different boundary condition		Variation continuous or in steps with no special equipment required
	Voltage-dependent parameters	Resistors and capacitors replaced by electronic circuits which have to be different for each different function of property—voltage dependence		Manual by means of switches or relays—no special equipment required
Cost	Input device	High	High	Low
	Circuit elements, constant parameters	Low	Low	High
	Circuit elements, varying parameters	Very high	Very high	High
	Indicating measuring devices	Low		Low
	Recording measuring devices	Very high	High	Low

for recording) is more expensive for the short-time than for medium- or long-time apparatus. However, in general, no recording (oscillographs) is being done with short-time computers, since the oscilloscope is less expensive than the recording devices used in medium-time and in long-time apparatus. Between the latter two, the long-time computer probably is less expensive in instrumentation than the medium-time, because the former permits the use of multiple-point recorders.

Conclusions

As usual when different alternatives to an engineering problem are analyzed, there is no general answer possible which would hold for all cases. The proper selection depends on a number of variables.

One can conclude that short-time computers are well-suited for a more qualitative analysis of problems with constant parameters. Medium-time computers have their field of greatest significance in problems with simple operating conditions and constant parameters. The long-time computer is the most versatile apparatus and, so far, is indispensable for complex problems and for nonlinear parameters. Table I summarizes the characteristics of the three kinds of computers given in this paper.

In way of example of problems for which the *HMFA* seems better suited than any of the other equipment, the following three should be mentioned:

SOLIDIFICATION OF METALS

A hollow cylinder (mold) of great length is initially at uniform temperature. At time zero, the cavity is filled with a liquid metal of constant temperature. Because of the temperature difference the metal starts to cool. After a short time interval the metal shrinks away from the mold and any heat transferred from the cooling metal to the mold must pass through a thermal resistance represented by the airgap. As the temperature drops further, the metal reaches the upper end of the solidification range. At that point, heat (heat of fusion) starts to be liberated and continues to flow until the lower end of the solidification range is reached. Thermal properties of the metal are different for liquid and solid state and should be changed at the mean average temperature of the solidification range. All these changes take place in each section, but at different times in each section.

Figure 7 shows a schematic time–temperature diagram with all required changes indicated. The circuit used to represent the first section of the mold and the first section of the metal is shown in Figure 8. The switch S_1 is opened at a predetermined time; the switch S_2 is operated twice at a predetermined time—once inserting the "heat of fusion" into the circuit and once disconnecting it. Finally, switches S_3 and S_4 are to be operated between the two actions of switch S_2, at a predetermined temperature.

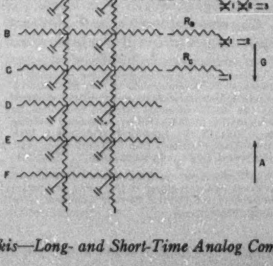
a. One-half "solid resistance"
b. One-half difference liquid-solid resistor
c. Solid capacitance
d. Difference below liquid plus solid
e. Heat of fusion, capacitance

REGENERATOR OPERATION

A second problem refers to the operation of a regenerator, such as used for open-hearth furnaces, glass-melting tanks, and so forth. In many regenerators, the hot combustion gases are blown through refractory ducts for a predetermined period. Then the gas is shut off and cold air is blown through in opposite direction. The cold air picks up some of the heat stored in the refractory walls.

To represent this process, the "reversal period" (gas time and air time, respectively) is divided into several time steps. During each time step a certain amount of gas or air flows into the refractory flue, and the gas (or air) has a certain heat content per degree temperature difference. Now a network is built to represent the refractory flue. Then, at time zero, the first "gas capacitor", charged to the "gas voltage" (temperature), is connected to the first "flue section" across a boundary resistance. See Figure 9. After a time equivalent to one time step has lapsed, the gas capacitor has lost part of its charge to the flue section and, accordingly, its voltage has decreased. Now it is connected through a different boundary resistance to the second flue section, and a second gas capacitor, again charged to the gas voltage, is connected to the first flue section. After the second time step has elapsed, the first gas capacitor is connected to the third flue section, the second gas capacitor, to the second flue section, and a third gas capacitor, to the first flue section. This procedure is continued until the "gas period" is exhausted. Now uncharged "air capacitors" are connected to the individual flue sections in opposite directions, the air boundary resistances being different from the gas boundary resistances.

Figure 9. Circuit representing regenerator



HOLLOW CYLINDRICAL THERMAL INSULATION

The third problem is a relatively simple one: that of intermittent operation of a hollow cylindrical thermal insulation, such as is used for steampipes. This problem can be set up easily on any one of the three types of analyzers. But the results, to be usable as general graphs, should be very accurate, and, therefore, again the long-time apparatus appears to be best.

Surge Protection in a Modern Watt-Hour Meter

F. H. BUSCH
MEMBER AIEE

G. D. WILLIAMS
NONMEMBER AIEE

RECENT trends in metering practice have imposed additional requirements upon the design of watt-hour meters, particularly from the viewpoint of surge protection. Most significant has been the change in the installation location, with the meter ahead of and remote from the fuse and switch box, and usually outdoors. This change, combined with the increasing number of meters installed on rural distribution systems, has indicated clearly that surge protection is of primary concern in evaluating the merits of any particular meter design.

Consideration of the over-all problem of surge protection for watt-hour meters is particularly appropriate at this time. Never before has the cost of labor in testing and maintaining the meters on a utility system been so great. In addition, maintenance of the growing number of meters installed on rural distribution systems, where lightning hazards are the most severe, is complicated by the greater distances involved.

Reduction of maintenance was the primary objective for the development of a new watt-hour meter, Figures 1 and 2. To accomplish this end, detailed consideration was given to the surge protection problem and to the provision of adequate protective features. By reducing the hazards of damage from surges, longer service periods without attention are possible. This objective has been further insured by other improvements. For example, the problem of bearing wear inherent in previous meter designs has been solved by suspending the rotor by means of two small magnets, one fixed to the meter frame and the other to the top of the shaft of the rotating disk. In this manner the previous use of a pivot or ball-on-sapphire bearing, operating at high-bearing pressures, has been eliminated.[1]

Types of Surge Protection Required

The modern meter, as exemplified by the design described in this paper, must be protected from surge current demagnetization of the permanent magnets and also from insulation damage caused by voltage flashovers. The types of protection and the meter components involved are as follows

A. Protection from demagnetization
   1. Braking magnets.
   2. Suspension magnets.

B. Protection from insulation damage
   1. Current coil.
   2. Potential coil.
   3. Terminals and mounting.

C. Protection from mechanical damage
   1. Disk and shaft.

That surge currents can be great enough to demagnetize the braking magnets is recognized. Damage of this type is of considerable concern to the operating company as it results in over-registration of the meter and, consequently, serious customer relation problems. During the last 15 years this hazard has been reduced effectively by using Alnico permanent magnets, or by encasing the magnets in a conducting covering.

The suspension of the meter disk and shaft by new magnetic components has been made possible by recent developments in magnetic materials. Protection of these magnets, as well as the braking magnets, must be provided.

Damage to insulation from lightning surges is the same for a watt-hour meter as for other electric equipment. The potential coil is made of many turns of small wire and is insulated from the frame or mounting of the meter. The most likely result of insulation puncture or flashover from the coil to the frame is the burnout of the small wire by either the surge current or the line-frequency ground current. This usually leaves the coil open circuited, and meter failure is evidenced by loss of registration. Meter current coils, on the other hand, are relatively heavy conductors and insulation puncture is not likely to result in open circuits. The hazard of short circuiting a portion of its turns is greater, however, and may result in under-registration of the meter. Terminal blocks or bases are subject to insulation flashover unless adequate insulation co-ordination is provided. The design considerations involved in providing this co-ordination are discussed in a later section of this paper.

The mechanical forces generated by severe surges can distort the watt-hour meter disk. A strong field in the current coils created by short circuit or surge current, acting on the aluminum disk, repels it violently, and may distort it sufficiently to prevent free rotation.

BRAKING MAGNETS

The braking magnets in the meter illustrated in Figure 3 utilize Alnico V, a highly coercive magnetic alloy having properties that make it especially suited to this application. Two C-shaped magnets are mounted diametrically opposite each other on a line passing through the axis of disk rotation. Actually they are cast as inserts in the die-cast aluminum alloy frame and are completely surrounded by the aluminum. Resistance to demagnetization by surge currents is attained by taking full advantage of the high-coercive force of Alnico V and by the eddy current shielding of the aluminum.

Alnico V has a coercive force of over 500

Paper 49-20, recommended by the AIEE instruments and measurements committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted July 19, 1948; made available for printing December 22, 1948.

F. H. BUSCH is section engineer and G. D. WILLIAMS is development engineer in the meter engineering division of the General Electric Company, West Lynn, Mass.

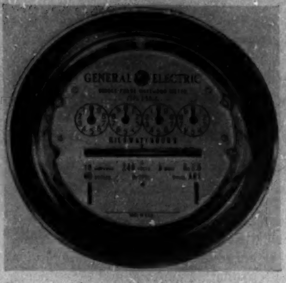

Figure 1. Detachable S-type single-phase watt-hour meter

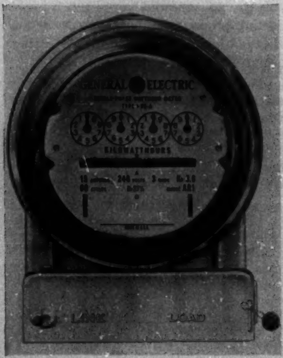
oersteds as compared with just over 200 for cobalt steel, and less than 100 for chromium or tungsten steel. This high-coercive force has permitted an improved method of providing the stabilizing knockdown given the magnets before use on meters. Previously, the method was to knock down the magnets a fixed percentage of their saturated strength. The improved procedure is to use a demagnetizing field of a uniform strength to give the magnets the stabilization desired. The strength of this demagnetizing field exceeds the field which would be produced in the meter by the highest short-circuit current to which the meter is expected to be subjected. This method gives positive assurance of the stability of the magnets against short-circuit currents. The new method eliminates a hazard inherent in the former method of per cent knockdown, in which a magnet of high residual but low-coercive force appeared satisfactory, even though the magnet lacked the basic property, coercivity, which gives it resistance to demagnetizing fields. Figure 4 shows the means of attaining this stabilization in terms of the demagnetization curve for Alnico V. Note in particular how a magnet having satisfactory saturated strength but poor coercivity can be readily detected and rejected when all magnets are subjected to a fixed value of stabilizing field. On the basis of saturated strength both magnets would appear to be equally satisfactory. The field to which all magnets for this meter are subjected is strong enough to demagnetize completely previous types of chrome-steel magnets.

Figure 2. Front-connected A-type single-phase watt-hour meter



The second way in which resistance to demagnetization by lightning surge currents is attained is the eddy current shielding provided by the sheath of high conductivity aluminum enclosing the magnets. Eddy currents induced in the shield are effective in substantially reducing the magnetic field produced by steep-front surge currents as has been described previously.[3]

How effective this modern design is in protecting against decalibration by lightning-type surges is shown by Figure 5 which gives the results of laboratory tests with surge current values up to 40,000 crest amperes through the neutral conductor of a detachable S-type meter installation. These results show its definite superiority (meter A) as compared with chrome steel or Alnico II magnets used in previous designs (meters B and C), for the condition of the conductors passing behind the meter vertically (V) or horizontally (H). A test wave of relatively slow time-to-crest was used to insure as pessimistic test data as possible.

SUSPENSION MAGNETS

Surge protection of the suspension magnets, which support the disk with negligible bearing load, is assured by the same features as those used for the braking magnets. The magnetic alloy used for both inner and outer magnets is Cunico which has a coercivity of 700 oersteds. Full advantage of this property is taken by subjecting all magnets to a strong stabilizing field which is greater than the field established by the maximum short circuit or lightning surge current expected. The same principles as shown in Figure 4 apply.

In addition, eddy current shielding is obtained by enclosing the outer magnet in a jacket of conductive die-cast material, as well as by mounting it in an aluminum support. The location of the magnetic suspension at the top of the disk shaft, Figure 6, is particularly desirable because of its distance from the current coils which are the source of surge or short circuit fields. The concentric design of the magnets also contributes to the surge resistance, since the inner magnet is effectively shielded by the outer magnet.

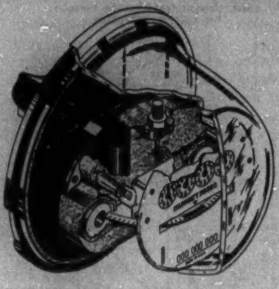


Figure 3. Cutaway diagram of new single-phase watt-hour meter showing location of braking magnets

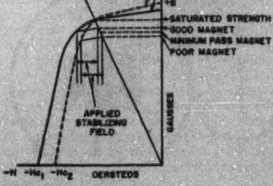
A number of meters with magnetic suspensions have been submitted to both 60-cycle short-circuit tests and to lightning-type surges. Special care was taken to observe any change in the vertical position of the disk that would indicate weakened magnets. Tests were made with 60-cycle short-circuit currents up to 15,000 amperes through the current coils of a 15-ampere meter and with lightning surge currents up to 40,000 crest amperes through the vertical neutral of a detachable S-type meter installation. Even with the use of a microscope, any change of disk position was difficult to detect and in no case was greater than 0.002 inch.

These tests also showed that no damage occurred due to the mechanical forces

Figure 4. Stabilization of highly coercive magnetic alloy by application of uniform demagnetizing field



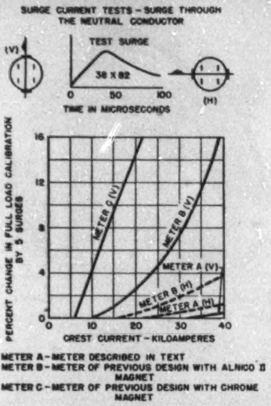


Figure 5. Curve showing results of lightning-type current surge tests on watt-hour meter calibration. Detachable-type meter

created in the disk by the surge current fields. Strength sufficient to prevent damage has been provided in this meter by a stiff aluminum disk, embossed to further increase its strength. This disk design has been used in previous meter designs and has proved satisfactory.

Insulation Coordination

The degree of improvement obtainable by practical improvements in sparkover levels of insulation cannot be expected to decrease substantially the hazard of surge damage to the meter insulations. Lightning discharges are considered to be the discharge of an electric charge between clouds and the earth. This discharge produces a current flow which will induce a voltage across any impedances encountered. The magnitude of the surge current and the steepness of its wave front are often such that the voltage induced across the meter windings would be many times the value to which it is limited by sparkover of the weakest point of insulation.

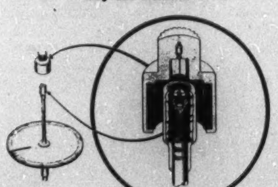

Figure 6. Magnetic suspension of rotating element of the new single-phase watt-hour meter with cutaway showing arrangement of magnetic elements

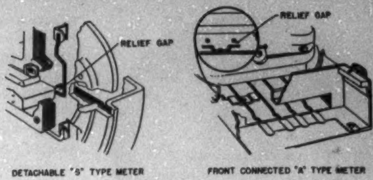

Figure 7. Cutaway diagrams showing location of relief gaps in new single-phase watt-hour meters

To reduce damage to the insulations to a minimum, the location of the sparkover point must be selected and predicted in the design, co-ordinating its impulse sparkover level with those of the other insulations. In the meter described, this has been accomplished by simple means. In the detachable S-type meter, brass pins riveted to the meter base provide controlled air gaps to the line leads. As shown in Figure 7 the pins are riveted through the base to stainless-steel spring clips which contact the lip of the socket when the meter is installed, thus completing the grounding circuit. Similarly, on the bottom-connected A-type meter, a formed clip provides the sparkover relief gap from the line leads to ground.

Figure 8 shows the improvement in appearance and mechanical nicety in the electromagnet design of this meter. Equally real, but not visibly evident, is the improvement in insulation strengths obtained. The current coils consist of round wire preformed to the required shapes. They are assembled onto the current laminations and held in position by means of a special mold. Butyl rubber is then molded and cured around the coils to provide for insulation both between coils and from the coils to the iron as well as to provide rigid mechanical positioning. This is in contrast to the usual practice of using taped or enameled wire coils which also must be separated from each other and from the lamination iron, usually by some form of paper or fiber.

Improved insulating techniques are also evident in the potential coil. Molding of the coil within an enclosure of polyethylene provides a straightforward solution to the difficulties of wrapping and insulating encountered with previous paper-insulated designs. The coil is layer wound with a thin insulating paper between each layer. The advantages of this construction in providing superior turn-to-turn and layer-to-layer insulation has been proved by many years of satisfactory experience. The enclosure of this coil within the molded polyethylene further improves the design by filling voids with insulating material and by reducing the possibility of corona as compared to previous constructions. The result is an increased impulse insulation level from windings to ground and also between the start and finish terminals of the coil.

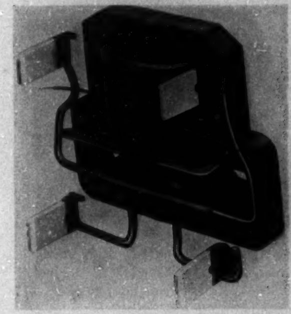

Figure 8. Electromagnet assembly of the new single-phase watt-hour meter

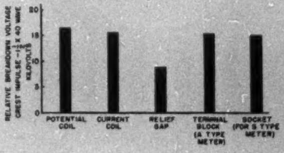
The requirement of long life was a major consideration in the choice of these materials for molding the current and potential coils. The improved sealing and omission of material provided by the molding processes materially reduces the effect of high humidity and insures higher insulation levels over a longer life.

The improved insulation strengths obtained permit satisfactory co-ordination of the insulation and the relief gaps. Fig-

Figure 9. Relative breakdown voltage of meter components showing co-ordination of insulation levels



ure 9 shows the insulation co-ordination by comparing relative impulse voltage breakdown levels of the components of the meter with the relief gaps. The impulse level of the socket used for installing the detachable S-type meter is also shown since it is such an important part of the installation for this type meter. Variations between individual meters and for different test conditions are to be expected.

Summary

The growing number of watt-hour meters being installed outdoors with the new installation sequence have clearly established the necessity for protection against lightning surge damage. In a completely new meter this has been accomplished to a remarkable degree. Laboratory tests with lightning-type surges show the design to be definitely superior to previous designs.

Effective use of magnetic alloys has been made, combined with the additional protection offered by the conductive sheath enclosing the braking and suspension magnets. The insulation design of the potential and current coils has been improved through use of recently developed materials and methods of construction.

Insulation levels have been co-ordinated so that surge voltages will sparkover at relief gaps which have been incorporated to provide controlled points for sparkover with a minimum hazard of meter damage.

Discussion

G. G. Waite (Sangamo Company, Ltd., Leaside, Ontario, Canada): Could the authors inform us of any statistics available as to the damage to meters from surges? Such statistics, with perhaps information as to the kind and extent of the damage, would be very relevant and would assist greatly in evaluating statements made in this paper.

F. C. Holtz (Sangamo Electric Company, Springfield, Ill.):

Braking Magnets

In order that the statements made in regard to the stabilization of magnets as used on watt-hour meters may not be misleading, it should be pointed out to the present authors that the practice of subjecting magnets to a "minimum" field for uniform stabilization is not new. For over twenty-five years, this has been the practice of the company with which I am associated. The magnets are subjected not only to a field in one direction, but to a revolving field which constitutes, in effect, a "washing" in the minimum field, so as to insure stability against stray-field demagnetization in substantially every direction. After such treatments, magnets with insufficient damping strength to meet the requirements of a particular meter are automatically rejected, as the authors indicate. Further demagnetization on the meter brings about correct calibration and adds further to surge resistance.

The use of modern magnet materials has in itself constituted the major gain in surge resistance. The effectiveness of any material is dependent upon its coercive force and the particular manner in which it is used. While the casting of magnets in aluminum or other metals is not new, the additional protection which it affords is achieved by other means, such as copper plating, or by designing the castings and brackets to which they are attached so that they provide short-circuited loops, preventing the rapid rise of magnetic flux within the areas they enclose.

As an indication of the extent to which surge-proofing has been attained, it may be said that, in the modern watt-hour meter using one of the better grades of Alnico magnet steel, not a single case of demagnetization from either short circuit or lightning surge has been brought to the writer's attention in the last nine years, since these meters were first introduced. In one instance where lightning had entered and where, perhaps because of a follow-up current, the lower bearing screw was burned off resulting in stopping the meter, the meter was found to be within calibration when the bearing was replaced. Such performance could not have resulted from some of the earlier-type meters; it was, in fact, their failure to withstand the effect of severe surges which brought about the general use of surge-resistant types. The ability to withstand these surges is a matter of engineering design and knowledge, and the modern meter can withstand repeated surges of a magnitude of the order indicated by the authors.

Insulation Co-ordination

The introduction of protective gaps in watt-hour meters has been suggested frequently as a means of preventing damage to its electric circuits. The effectiveness of such arrangements is dependent upon a number of conditions which should receive careful consideration. It must be said, however, in defense of such an arrangement that it does, as the authors point out, provide a weak link where, under favorable conditions, a surge may be by-passed to ground. When this occurs between electrodes, the path soon may be deionized and the insulation of the meter circuits restored. Had such surges taken place over insulating materials, a carbonized path might have been formed which would result in a power follow-up and resulting destruction of the meter. Where protective gaps are provided, as in the author's meter, the proper functioning may depend to a degree upon the available power level, in addition to the disruptive effect of the initial surge. Similar arrangements received the attention of the Sangamo Electric Company in 1937, at which time the subject was being discussed rather vigorously. Safety gaps of approximately 0.06- to 0.08-inch opening were placed between current-coil leads and ground. With the meter connected to a transformer of approximately 6-kilovolt-ampere capacity, it was possible to apply repeatedly a steep-front surge by means of a synchronized surge generator; the surge would discharge over the gaps and only show, at most, two to six cycles of power follow-up.

A possible improvement suggested itself in the form of a compression gap, comprised of rivetting a copper button into the inside surface of the meter base, adjacent to the heavy copper straps which connected to the main terminals. A porcelain bushing was placed over the button, just filling the space between the base and strap, thus providing what might be termed a compression gap with a specified opening. This type of gap gave more uniform results and led to power follow-up of not more than two cycles, even under the influence of heavy surges. This type of gap was pronounced superior to the open type and was considered satisfactory. A review of the tests then brought up the question of what might happen in the event the meter was connected by relatively low-resistance leads to a source of relatively high-power level.

The experiments therefore were repeated using two 50-kva transformers in parallel, having no limiting reactance or resistance in series except for the connecting cables. Several tests using the open gap indicated that serious damage resulted from power follow-up; except for the placement of an 80-ampere fuse in the ground circuit, the meter might have been destroyed. It also was observed that discharge frequently took place through air in other parts of the meter, where the separations were appreciably greater than in the protective gap.

Further tests made on the compression gap gave equally discouraging results because of power follow-up under the conditions mentioned in the preceding paragraph.

A review of the data at this time indicates that, whereas the crest values of the impulses used at that time were of somewhat the same order as those used by the authors, it is possible that protective gap openings somewhat larger than 0.06 to 0.08 inch might have lowered the power follow-up current.

A high insulation level in a watt-hour meter is most desirable, which raises the important question of preventing breakdown versus providing a weak link with the possibility of power follow-up damage. It would be interesting to have some further figures on the behavior of the authors' protective gaps when the meters are placed adjacent to large power transformers.

We might also ask for more information as to the magnitude of the gap spacings and how they are maintained in the ordinary process of manufacture.

F. H. Busch, G. D. Williams: The principal portion of the discussion presented by F. C. Holtz deals with the insulation co-ordination of this modern watt-hour meter. He agrees that a high insulation level in a watt-hour meter is most desirable. Next the question of preventing breakdown versus providing a flashover point is raised.

It must be made clear that the insulation voltage strength of this meter has been maintained at the same high level which has been found satisfactory through many years of experience. In the design of the new meter, it has been recognized that all breakdowns caused by surges cannot be prevented. This issue is not ignored, however, but rather the meter is designed to direct the puncture from any excessively high voltage to the point where it will do the least damage. This has been achieved by improving the insulation level of all the parts as compared to the present art, with the exception of the relief gap which is designed at the same level. In this way failure does not occur through or across organic insulation where a carbonized path might be formed, as pointed out by F. C. Holtz.

No attempt has been made to include a lightning arrester in the meter, but rather the emphasis has been to give the best coordination in insulation levels, taking maximum advantage of the properties of materials available commercially.

C. G. Waites' question concerning statistics available as to the damage to meters from surges, can be answered only to the extent that, to the author's knowledge, there are no comprehensive and sufficiently detailed data that permit ready evaluation. Various lightning investigations have shown the wide diversity of experience that occurs from place to place and from year to year. Since rural distribution systems notably offer greater exposure to lightning, the recent invesigation reported by MacCarthy, Stann, Edge, and McKinley should be pertinent.[1] It is interesting to note that the maximum values of discharge currents found in their study are approximately 30 kiloamperes, which is lower than the maximum currents used in the surge tests reported in this paper.

A New Thermal Volt-Ampere Demand Meter

M. E. DOUGLASS
NONMEMBER AIEE

W. H. MORONG
NONMEMBER AIEE

THE PURPOSE of this paper is to describe the principles and to show the performance of a new meter for measuring single-phase volt-ampere demand, using thermal means. The discussion is limited to the technical principles and performance of such a meter, and does not consider the problems of rate structures and their relation to the units of demand measurement.

A study of the general problem of kilovolt-ampere measurement some years ago showed at least 40 patents issued on various methods of measuring and registering kilovolt-amperes. Many of the methods used required integrating devices and timing mechanisms to obtain a measurement of the demand. Since kilovolt-ampere-hours as such are used very little, thermal means of registering kilovolt-amperes, eliminating the integrating intermediary, are particularly adaptable. Table I, while not a complete summary of all the detailed methods proposed for measuring kilovolt-ampere does list the basic methods of combining the more common primary detectors with auxiliary devices to give an indication of volt-ampere demand.

Operating Principles

Of the four methods shown in Table I of using watt-hour meters and reactive volt-ampere-hour meters, all have been used to some extent.

In the first three methods, the requirement of two integrating units as primary detectors, and the complication of the ball mechanism or calculation of the vector sum of the meter indications, makes any one of them a relatively expensive means of obtaining billing information, justified only on large loads. The methods do provide true vector addition of active and reactive power to give volt-amperes.

The fourth method, that of adding the meter rotations through a series of differentials, requires many precisely made parts to minimize the friction load of the differentials and over-riding clutches, in addition to the problems of the first three. It indicates an approximation to kilovolt-ampere-hours or demand, good over a wide range of power factors.

The method of shifting the phase of the potential excitation of the watt-hour meter by the amount necessary to compensate for the average power factor angle of the load has been used. Devices of this kind measure a quantity that can be described by

$$EI \cos (A-B)$$

where E and I are voltage and current respectively, A is the power factor angle, and B is the angle of lag of the potential excitation. The registration is exact only when the power factor angle and the potential excitation lag angle are equal; the method, however, will permit deviations of about ± 11.4 angular degrees between A and B with errors of ± 1 per cent. To extend the range of power factors of this method, two or more watt-hour meters, with different values of B, may be combined through differential gearing. This is, of course, subject to the same comments on size and expense as the active-reactive vector addition methods mentioned in the preceding paragraphs.

In using an ampere-hour meter to give an indication of kilovolt-amperes, a shading coil, positioned by voltage, is inserted between the pole faces of the meter. The shading coil is suspended as a pendulous element in the air gap of the meter, with a torque to position the coil applied from an electromagnetic unit operated by voltage. The scheme provides a registration of kilovolt-amperes over a range of voltage, but it requires very careful leveling and mounting.

Thermal meters in both wattmeter and ampere meter form have been used for kilovolt-ampere measurement. Shifting the phase of the potential excitation (as described for watt-hour meters) is a method of obtaining an approximation to kilovolt-amperes over a range of power factors using a thermal wattmeter. The limitations of the method are the same as for the phase shifting method with a watt-hour meter. Multiplying the reading of an ampere meter by an assumed constant voltage is a method that has been used for measuring kilovolt-amperes with a thermal ampere meter. This method is obviously subject to errors due to line voltage differing from the assumed value.

Because all of these methods of registering kilovolt-ampere demands have either cost, maintenance, or accuracy problems involved in their application, they have not been used widely, and the extension of kilovolt-ampere metering rates by those who want them has been hampered. To meet the needs of those who wish to measure kilovolt-amperes demand, a parallel-circuit, voltage-compensating scheme for a thermal ampere meter to give an indication of kilovolt-amperes over a range in voltage has been developed.

Description of New Meter and Operation

An elementary diagram of the electrical circuit of the new meter is shown in Figure 1. The basic elements of the device are the bimetallic spirals, Figure 2; a resistance valve Figure 4; a load compensating resistor Figure 4; and the current and potential transformers.

Paper 49-22, recommended by the AIEE instruments and measurements committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 15, 1948; made available for printing January 7, 1949.

M. E. Douglass and W. H. Morong are both with the General Electric Company, West Lynn, Mass.

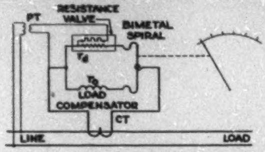

Figure 1. Thermal kilovolt-ampere-demand meter circuit diagram

The bimetallic spirals are thermally insulated so their temperature rise is directly proportional to the energy dissipated. They have the same torque change per unit temperature change, and are connected in opposition on a common shaft. The deflection of this shaft from the position of equal bimetallic temperatures is proportional to the temperature difference of the bimetallic spirals, and hence to the difference in energy input to the spirals.

The resistance valve is a temperature-sensitive resistor thermally coupled with a heating element, the assembly being encased in a glass envelope. The heating element is energized by the potential transformer; hence, its temperature, and the temperature of the associated resistor, is a function of voltage.

The load compensating resistor is a temperature-sensitive resistor, so adjusted that its resistance change as a function of current balances the resistance change as a function of current of the temperature-sensitive resistor in the resistance valve.

As current is drawn by the load, a current proportional to it flows in the secondary circuit of the current transformer. This secondary current divides between the two parallel circuits inversely proportional to their total resistances. Since the resistance of one side of the parallel circuit is a function of voltage, the ratio of the currents, and, hence, the difference in energy dissipated in the bimetallic spirals (that is, pointer deflection) is a function of voltage. As the line current changes, the difference in currents in the two branches of the circuit changes proportionally. Thus, the difference in energy dissipated in the two driving

* General classification of method of meter described in the paper.

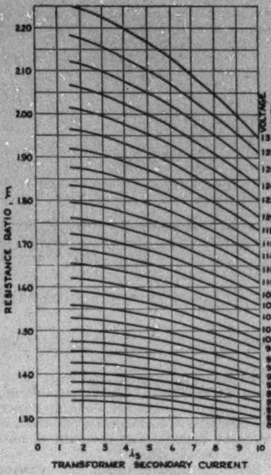

Figure 5. Curves of voltage, m, and i_s

spirals is a function of line voltage and line current.

For a correct volt-ampere indication, the deflection of the shaft, Θ, should be given by an expression which is of the form

$$\Theta = K_1(EI)^n \qquad (1)$$

where K_1 is a proportionality constant, E is the line voltage, I the line amperes, and n is an exponent of volt-amperes. This equation may be rewritten to be

$$\Theta = K_1E^nI^n \qquad (2)$$

which means that, for a correctly operating volt-ampere meter, the deflection must change according to the same function of volts and amperes over the range of voltage and current for which the device is to be used.

With the thermal unit and circuit described previously, the deflection of the shaft is given by the expression

$$\Theta = K_2 i_s^2 \left[\frac{kR_h \frac{m^2}{(m+1)^2}}{1 - ai_s^2 \frac{m^2}{(m+1)^2}} - \frac{R_c \frac{1}{(m+1)^2}}{1 - bi_s^2 \frac{1}{(m+1)^2}} \right] \qquad (3)$$

where K_2 is a proportionality constant, i_s is the transformer secondary current, k, R_h, a, R_c, and b are constants of the design, and m is the ratio of resistances of the parallel branches of the circuit. Equation 3 is derived in the Appendix.

Since in equation 3 the exponent of the secondary current, i_s, is two, the exponent n in equation 2 must also be two. Thus the expression in parenthesis in equation 3 must be proportional to the voltage squared, that is

$$\left[\frac{kR_h \frac{m^2}{(m+1)^2}}{1 - ai_s^2 \frac{m^2}{(m+1)^2}} - \frac{R_c \frac{1}{(m+1)^2}}{1 - bi_s^2 \frac{1}{(m+1)}} \right] = K_3E^2 \qquad (4)$$

where K_3 is a proportionality constant, and E is line voltage.

The term m is given by the expression

$$m = \frac{r_d + r_c}{r_o + r_h} = \frac{i_h}{i_c} \qquad (5)$$

where r_h and r_c are the resistances of the hot and cold spirals respectively, r_d and r_o are the resistances of the resistance valve and load compensator respectively and i_h and i_c are the current in the hot and cold spirals respectively.

Since r_d, equation 5, is the only component of m which is a function of voltage, the design problem is to make r_d change with voltage and current in such a way that m is the correct function of voltage and current to satisfy equation 4.

A solution of equation 4 is shown in Figure 5. In this illustration the transformer secondary current, i_s, is the abscissa and the resistance ratio, m, is the ordinate. On this co-ordinate system are plotted voltage index lines. From Figure 5, the required change in m to satisfy equation 4 can be found for any change in voltage or current. The required change in the resistance valve, r_d, can be calculated from equation 5.

Resistance Valve

Considering the resistance valve, as the voltage across the heater is increased, the temperature and resistance of r_d rise. This change of resistance with voltage may be expressed by the equation

$$\dot{r}_{de} = r_d \alpha \dot{\tau}_r \eta \dot{q}_h \qquad (6)$$

where $\dot{r}_{d_e}$ is the rate of change of r_d with voltage, α is the temperature coefficient of resistance of r_d, $\dot{\tau}_r$ is the rate of temperature change of r_d with heat input to it, η is efficiency, or the fraction of heat input to the heater that reaches r_d, and $\dot{q}_h$ is the rate of change of heat input to the heater with voltage.

The heater is not the only source of heat to r_d, however. The current passing through r_d also generates heat which causes changes in r_d as a function of current. This resistance change with current may be expressed by the equation

$$\dot{r}_{dl} = r_d \alpha \dot{\tau}_r \dot{q}_l \qquad (7)$$

where $\dot{r}_{dl}$ is the rate of change of r_d with current, α and $\dot{\tau}$ are the same as above and $\dot{q}_l$ is the rate of change of heat input to r_d with current.

Since the purpose of r_d is to change the ratio of currents, m, as a function of voltage independent of current, the value of $\dot{r}_{dl}$ must be minimized, and any residual value must be compensated by changes in the load compensator r_o. To make $\dot{r}_{de}$, the voltage sensitivity, large, it is necessary to have the items that make up the voltage sensitivity on the right hand side of equation 6 large. The first three items, however, r_d, α, and $\dot{\tau}_r$, are also components of $\dot{r}_{dl}$ which it is desirable to minimize. Thus, η, the efficiency of heat transfer and $\dot{q}_h$, the rate of heat input to the heater with voltage are the items that can be manipulated in design to best advantage.

Heat transfer by radiation increases with temperature much more rapidly at high temperatures than at low temperatures; for this reason, it was found desirable to transfer heat from heater to r_d by radiation. This was done by mechanically arranging the parts of the resistance valve so that r_d was in the form of a helically-wound ribbon with a straight rod of heater material on its axis. It is not

Figure 6. Temperature error curves

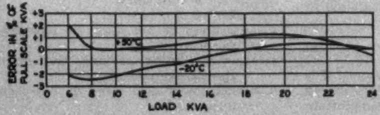

Figure 7. Voltage error curves

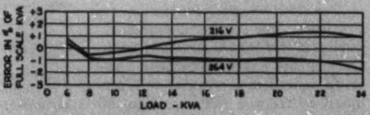
Type *IHE-1* single phase watt-hour and thermal volt-ampere demand meter, 50 amperes, 240 volt, 60 cycle, 3 wire
Voltage curve-demand meter element
Power factor = 1.0



within the scope of this paper to treat the heat transfer method in detail. It can be shown, however, that with adequate shielding to conserve stray radiation, the factor η is not constant but is an exponential function of voltage that increases rapidly with voltage in the operating range. Thus an additional gain in r_{de} is realized by utilizing this heat transfer method that makes the efficiency of heat transfer a function of voltage. The shielding to conserve stray radiation consists of a double-walled cylinder of thin, bright nickel, closed at both ends except for openings for the leads, mounted concentrically about the heater and control resistance, r_d.

To make the value of $\dot{q}_h$, the rate of heat input to the heater with voltage, as large as possible, a heater material with a negative temperature coefficient of resistance is desirable since increasing voltage increases the heater temperature, and if, at the same time, this increase in temperature reduces the heater resistance, a further gain in heat input with voltage can be made. The material carbon fulfills these requirements; hence, it was the heater material selected.

With the factors η and $\dot{q}_h$ made as large as possible, it remains to compensate the heating effects of current in r_d. This was accomplished in two ways. It was found that the radiation loss from r_d could be minimized by providing an additional path for the conduction of heat, through the medium of an inert gas in the envelope. The presence of the gas also reduces the efficiency of heat transfer from the heater to r_d but the reduction in voltage sensitivity is not as great as the reduction in current sensitivity. Balancing one effect against the other to arrive at an optimum operating condition was done by controlling the pressure of the gas. It is known that the heat conductivity of a gas is proportional to the pressure, if the pressure is reduced to the point where the conduction path is shorter than the mean free path of the molecules. Thus, by controlling the gas pressure, an optimum ratio of voltage sensitivity to current sensitivity could be obtained. Helium, having the highest conductivity of the inert gases, provided the greatest degree of control.

The finally remaining current sensitivity of r_d was balanced by a temperature-sensitive resistor of nickel wire for r_o. The nickel wire was wound in the form of a helix. The cold or no current resistance of this helix is controlled by the diameter and length of the wire. The change in resistance with current is controlled by the wire diameter, helix diameter, and turn spacing, since these factors control the heat escape versus temperature characteristic of the helix.

Performance

With the use of temperature-sensitive elements in the meter, it might be imagined that ambient temperature would greatly affect the readings. This is not the case however, since in general the effects of ambient temperature are balanced in both the mechanical and electrical circuits of the meter. There is a net temperature effect on the meter that is compensated by a bimetallic spiral connected through a linkage to the thermal unit shaft. Performance curves on the meter, Figure 6 show that temperature variations from −20 degrees centigrade (−4 degrees Fahrenheit) to +50 degrees centigrade (122 degrees Fahrenheit) cause errors of less than ±3 per cent of full scale from one-quarter full-scale load to full-scale load.

The registration of the meters as a function of voltage and load is shown in Figure 7, and shows that for a range of ±10 per cent in voltage, the meters register within ±2 per cent of the correct value from one-quarter full-scale load to full-scale load.

The full-scale torque of the meters is 850 gram-millimeters with a power consumption of six watts in the potential circuit, and about 14 watts in the current circuit at full scale.

Power factor obviously does not influence the meter registration of kilovolt-amperes since the only interaction between voltage and current comes in the thermal coupling in the resistance valve. In Figure 8 is shown a finished, practical meter in combination with a watt-hour meter for registering kilowatt-hours and kilovolt-amperes demand.

Appendix. A New Thermal Volt-Ampere Meter

The purpose of this Appendix is to derive equation 3 quoted in the body of the paper.

As stated previously, the bimetallic shaft deflection is proportional to the difference in energy input to the bimetallic spirals. This is true only if the temperature rise per unit of energy input is the same for both spirals. Considering the general case, where this condition may not be met, the deflection of the thermal unit shaft will be given by equation 8

$$\Theta = K(kW_h - W_c) \tag{8}$$

where Θ is the deflection of the shaft, K is a proportionality constant between energy and deflection, k is the ratio of temperature rise per unit of energy input of the spirals, and W_h and W_c are the energy input to the hot and cold spirals respectively.

The energy input to the spirals is given by equations 9 and 10

$$W_h = i_h^2 r_h \tag{9}$$

$$W_c = i_c^2 r_c \tag{10}$$

where i_h and i_c are the hot and cold spiral currents respectively, and r_h and r_c are the hot and cold spiral resistances respectively.

Since resistance of the bimetallic spirals is not constant, but is a function of the temperature of the spiral, the resistance will be a function of current. This function is given in equations 11 and 12

$$r_h = \frac{R_h}{1 - a i_h^2} \tag{11}$$

$$r_c = \frac{R_c}{1 - b i_c^2} \tag{12}$$

where R_h and R_c are the no-current resistances of the hot and cold spirals respectively, and a and b are constants depending upon the temperature coefficient of resistance of the spiral material and upon the thermal insulation of the spiral.

From the parallel circuit the relations given in equations 13, 14, and 15 are obtained

$$i_c + i_h = i_s \tag{13}$$

$$i_c = i_s \frac{r_2}{r_1 + r_2} = i_s \frac{1}{m+1} \tag{14}$$

$$i_h = i_s \frac{r_1}{r_1 + r_2} = i_s \frac{m}{m+1} \tag{15}$$

where i_s is the secondary current of the transformer proportional to load current, r_1 is the total resistance of the resistance valve plus the cold spiral $(r_d + r_c)$, r_2 is the total resistance of the load compensator plus the hot spiral $(r_o + r_h)$, and m is the ratio of r_1 to r_2.

By substituting values from equations 9, 10, 11, 12, 13, 14, and 15 in equation 8, the expression for the deflection of the meter is obtained

$$\Theta = K i_s^2 \left[\frac{kR_h \dfrac{m^2}{(m+1)^2}}{1 - a i_s^2 \dfrac{m^2}{(m+1)^2}} - \frac{R_c \dfrac{1}{(m+1)^2}}{1 - b i_s^2 \dfrac{1}{(m+1)^2}} \right] \tag{3}$$

Symbols

Θ = deflection of bimetallic shaft, angular degrees
W_h = watts dissipated in hot spiral
W_c = watts dissipated in cold spiral
k = ratio of temperature rise per watt of hot spiral to temperature rise per watt of cold spiral
i_h = current in hot spiral
r_h = resistance of hot spiral
i_c = current in cold spiral
r_c = resistance of cold spiral
R_h = resistance of hot spiral at reference temperature
a = constant relating resistance to current through temperature rise
R_c = resistance of cold spiral at reference temperature

b = constant relating resistance to current through temperature rise
i_s = secondary current of current transformer
$r_1 = r_d + r_c$ = total resistance of cold spiral branch
$r_2 = r_o + r_h$ = total resistance of hot spiral branch
$m = r_1/r_2 = r_d + r_c/r_o + r_h$
K = proportionality constant between differential watts and deflection
K_1 = proportionality constant between volt-amperes squared and deflection for theoretically perfect meter
E = line voltage
I = line current
n = exponent of volt amperes

Discussion

G. G. Waite (Sangamo Company, Ltd., Leaside, Ontario, Canada): I would like to lend support to Perry Borden's suggestion that references to the prior art, be amplified in papers such as this one. Further, I can see no good reason for excluding references to patent numbers, as the authors have done.

The authors claim errors of less than 3 per cent of full scale for stated conditions of temperature and load, and 2 per cent for variations of 10 per cent in voltage. This is, perhaps, quite good considering the complexity of the compensation methods required. Why, however, do they choose to refer to only a ±1 per cent error for ±11.5 angular degrees deviation in the phase-shift method mentioned earlier in the paper, while talking about larger errors for their method?

M. E. Douglass, W. H. Morong: In regard to Waite's comments on accuracy of volt-ampere registration, we feel that a comparison of errors in two measuring methods should be referred to the same variable. With the new, thermal, volt-ampere demand meter the indication is independent of power factor, since the only interaction of voltage and current is obtained through the thermal coupling of the resistance valve; hence, the error caused by varying power-factor angle is zero. Furthermore, the quoted values of 2 and 3 per cent errors, given for the over-all performance, should not be compared with the fundamental error of the method only in the phase-shifting method. The selection of ±1 per cent was used purely as a convenient number to remember. The following table may help in clarifying the magnitude of the power-factor errors fundamental in the phase-shifting method. To these fundamental errors must be added any errors incidental to the measuring equipment.

It should be pointed out that the device must be calibrated to read one per cent fast at the assumed operating conditions to obtain the ±1 per cent error for ±11.5 angular degrees deviation from the assumed condition.

With regard to the complexity of the compensation: although the algebraic manipulations required to define the required compensation might be considered complex, the temperature coefficient of resistance of a metal, as an operating mechanism seems to us quite simple.

Synopsis: This paper presents the theory and describes the development of a simple, reliable, and compact optical shutter which utilizes a Kerr cell as a light valve. With the aid of such a shutter, routine photographic studies of electric discharges have been made using an effective exposure time of 0.000,000,04 second. The novel feature of an electro-optical or Kerr cell shutter is that there are no mechanical moving parts, the speed of operation depending only upon the rapidity with which a required voltage can be applied to the Kerr cell electrodes. These electrodes are immersed in a fluid which exhibits uniaxial birefringence when under the influence of an electric field. Electrical birefringence is described and explained at some length and the optical transmission of a Kerr cell shutter as a function of applied voltage is derived and plotted for reference. With the advent of the "all-electric" shutter, some of the latest techniques of the electronic art become applicable to photographic work. The control can be made sufficiently positive and accurate to permit initiation of operation at any preselected instant with a precision of 5×10^{-9} second. This excellence of control has made possible the detailed photographic study of light from very rapidly changing self-luminous objects. The complete components of an electro-optical camera are described in some detail. Prints are included which show photographic records of the electrical vaporization of a fine wire taken with an effective exposure time of 0.000,000,04 second. Comments are made on the ultimate possibilities and further application of Kerr-cell shutters for ultra high-speed photographic work.

The phenomenon of electrical birefringence was discovered by J. Kerr in 1875.[1] One of the early applications of this effect was made in the construction of a light valve, now commonly called a Kerr-cell shutter, for the measurement of very small time intervals.[2] The ordinary Kerr cell is composed of two flat plates or electrodes immersed in a fluid which becomes birefringent upon the application of an electric field. When such a cell is oriented between two polarizers crossed for minimum transmission the arrangement constitutes an optical shutter. With no voltage applied to the cell, light cannot be transmitted because of the crossed polarizers. A voltage applied to the electrodes has the effect of altering the state of polarization of the light, and transmission through the second polarizer is accomplished.

The very small time lag between the application of voltage to the electrodes and the appearance of birefringence has led to the application of such shutters to: measurement of the time lag in fluorescence;[3] study of early stages in spark discharges;[4] spectral studies of electric discharges;[5] measurement of the velocity of light;[6] and modulation of light in telephotography.[7] In the first three activities listed, an electro-optical shutter was connected across a spark gap by means of an adjustable length of transmission line. As the gap voltage was increased the shutter opened. The occurrence of a discharge caused the cell voltage to collapse suddenly at a time which depended upon the length of the transmission line between the gap and the Kerr cell electrodes. By this means various stages during the spark discharge were examined. The last two programs listed utilized Kerr cells with varying voltages applied to their electrodes. There was, however, no intention of developing an optical shutter for use in a camera. In 1926 J. W. Beams introduced the first full cycle (closed-open-closed) shutter using an arrangement of two Kerr cells.[8] A preliminary review of published literature has indicated that no completely controlled full cycle operation of a Kerr-cell shutter for photographic purposes thus far has been reported. Such work, however, may have been done during the war. This very practical application has been slow in coming because successful optical shutters of large aperture require the accurate timing and control of high voltages. Interest in the photography of very high speed phenomena has increased steadily in recent years, and the development of the electric art has been so rapid, that simple techniques for generating and switching high voltage pulses, with great precision, are now standard practice.

The information presented in this paper is the result of work done in one part of a proposed program of basic research on electrical discharges. In order to make a complete optical study of a phenomenon with a duration of a few microseconds, it was necessary to use a camera with a very accurate controllable shutter that would enable the attainment of exposure times of less than a microsecond. The electro-optical shutter was chosen as the only solution to this problem. By controlling the type, duration, and instant of application of the voltage pulse applied to the cell electrodes, photographic records with an effective exposure time of 0.000,000,04 second have been obtained at preselected intervals during the life of the phenomena being studied.

The Electro-Optical Kerr Effect

If a beam of polarized light is passed through a medium which is optically anisotropic, the velocity with which the light travels in the material depends upon the direction of the electric vector in the incident light. This means the substance is birefringent, that is, the index of refraction depends upon the direction

Paper 49-24, recommended by the AIEE instruments and measurements committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted June 25, 1947; made available for printing January 7, 1949.

At the time this paper was written, A. M. Zarem was head, and F. R. Marshall and F. L. Poole were members of the electrical subsection, physics section, United States Naval Ordnance Test Station, Pasadena, Calif.

A. M. Zarem has since become chairman of physics research for the Stanford Research Institute, Stanford, Calif., and director of the Los Angeles division, Los Angeles, Calif.

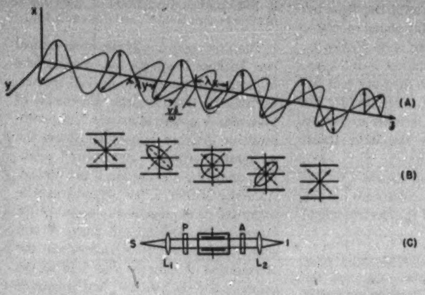

Figure 1. Principle of operation of a light valve

of propagation and the plane of polarization of the light traversing the medium. There are many known substances which are normally isotropic, but which exhibit the property of optical birefringence when subjected to an electrostatic field. This phenomenon is known as the electro-optical Kerr effect.[9]

In a simple case of a uniaxial birefringent material, there is one axis along which the index of refraction is not dependent upon the direction of the electric vector in the incident light. This axis is termed the optic axis of the material.[10] Substances which exhibit the electro-optical Kerr effect become uniaxially birefringent under the influence of an electric field, the optic axis being in the direction of the field.

According to the present state of the theory, the electro-optical Kerr effect is related intimately to molecular structure. It has been found that for a liquid or gas to exhibit a Kerr effect, it is essential that the individual molecules possess an aeolotropic optical polarizability with respect to a set of axes in the molecule. In addition, however, the molecules must have either a permanent dipole moment or be anisotropically polarizable by the application of an electric field, or both. It is not surprising, therefore, that the materials with the largest Kerr constants also have high dielectric constants.[11,12]

The statistically random orientation of molecules for liquids and gases in the normal state results in a condition of optical isotropy. In general, the application of an electric field produces a polarization assymmetry and also a tendency for the molecules to prefer a definite orientation mainly because of the permanent dipole moment. The orienting effect, although opposed by the thermal molecular motion, results in a more or less statistically-average regular arrangement of molecules under the influence of the applied electric field. Under these conditions the substance exhibits an overall molecular assymmetry and, generally, optical anisotropy. Orientation of the molecules is not a necessity, however, as the induced electrical polarization alone will cause optical anisotropy, but for substances with high Kerr constants, molecular orientation accounts for the largest part of the Kerr effect.[13] The rapidity with which the molecules of a substance assume a statistically-average preferred direction of orientation is related to the chemical structure, viscosity, and other factors, and can be determined approximately, using certain simplifying assumptions, by introducing the concept of relaxation time. The relaxation time for the Kerr effect is an average molecular time constant which may be considered as a measure of the effective time required for a substance to return to its optically isotropic state, after the electric field has been removed. For many substances this time is of the order of 10^{-9} second.[14]

Description of the Kerr Effect

For a clearer picture of the influence of an electric field upon a liquid which exhibits the Kerr effect, consider the arrangement of lenses L_1 and L_2, polarizers P and A, and the Kerr cell in Figure 1(c). S is a light source and I is its optical image. A beam of light, plane polarized at an angle φ with respect to the applied electric field, enters the cell. The electric vector in the incident light may be resolved into two components, one parallel and the other perpendicular to the applied field. These components traverse the cell fluid with different velocities, and as a result possess different wave lengths, as shown (much exaggerated) in Figure 1(a). As a consequence, if the applied electric field is kept fixed, the two components will differ more and more in space phase as they proceed through the liquid. This is the equivalent of stating that there will be a continuously increasing difference in time phase between the two components of light as they traverse the cell. Since the state of polarization of the light at any point is dependent upon the difference in time phase between the two components, the resultant light emerging from the cell will in general no longer be plane polarized. If the angle φ of the plane of polarization upon entering is 45 degrees, and the angular time phase difference between the components, δ, is an odd multiple of $\pi/2$, the light will become circularly polarized. If δ is an odd multiple of π, the emergent light will be plane polarized at 90 degrees to the plane of polarization of the entering light. For δ equal to an even multiple of π, the light leaves polarized as it entered. For all other values of δ the light will be elliptically polarized. The sketches of Figure 1(b) illustrate the states of polarization for $\delta = 0, \pi/4, \pi/2, 3\pi/4$, and π. The latter value represents the condition for full-open operation of the shutter.

One of the factors which determines the angular time phase δ is the Kerr constant of the fluid. The Kerr constant is defined by the equation

Table I

Substance	Kerr Constant	Resistivity	Dielectric Constant
Carbon disulphide CS_2	3.6×10^{-7}	10^{16}	2.5
Chloroform $CHCl_3$	-3.2×10^{-7}	10^{8}	5.0
Acetone C_3H_6O	16×10^{-7}	10^{7}	20.0
Nitrobenzene $C_6H_5NO_2$	400×10^{-7}	10^{10}	36.0

$$\frac{n_x - n_y}{\lambda} = KE^2 \tag{1}$$

where

n_x = refractive index in a direction parallel to the electric field
n_y = refractive index in a direction perpendicular to the electric field
λ = wave length in vacuo of the incident light in centimeters
E = applied electric field in electrostatic units

The time phase angle, see Appendix I, is given by

$$\delta = 2\pi l K E^2 \tag{2}$$

where

l = length of the light path under influence of the electric field in centimeters
E = applied electric field in electrostatic units
K = Kerr constant for the substance in centimeter-gram-seconds electrostatic units

Table I contains approximate Kerr constants, dielectric constants, and resistivities for various substances of interest in electro-optical work.

The Kerr constant for most substances depends not only upon temperature, but is a function of the wave length of the incident light as well. However, this is not too serious a difficulty even when careful quantitative work is to be done. It is a simple matter to keep the cell at constant temperature, and optical corrections for dispersion in the Kerr effect can be easily provided. These corrections were not required in the work described below.

Electro-Optical Characteristics of a Kerr Cell Shutter

The percentage optical transmission of a Kerr cell shutter[15] as a function of the applied electric field, may be obtained as in Appendix II, with the aid of equations 1 and 2 as

$$_{\varphi}T_{\alpha}=50[\cos^2(\varphi-\alpha)-\sin 2\varphi \sin 2\alpha \sin^2 \delta/2] \text{ per cent} \quad (3)$$

where

φ=angle between the plane of polarization of the entering light and the applied electric field

α=angle at which the analyzer is set relative to the applied electric field

$\delta=2\pi lKE^2$, angular time-phase difference between the emerging components of light parallel and perpendicular to the applied electric field

$_{\varphi}T_{\alpha}$=per cent optical transmission when the polarizer and analyzer angles are φ and α respectively

For optimum operation as a shutter, φ equals 45 degrees and α equals -45 degrees and the transmission therefore becomes

$$_{\pi/4}T_{-\pi/4}=50[\sin^2 \delta/2] \text{ per cent} \quad (4)$$

$$_{\pi/4}T_{-\pi/4}=50[\sin^2 (\pi lKE^2)] \text{ per cent}$$

If the electric field required for full-open operation is taken to be E_0, corresponding to an applied potential difference V_0, the transmission as a function of the potential difference, v, applied to the cell may be written:

$$_{\pi/4}T_{-\pi/4}=50\left[\sin^2 \frac{\pi}{2}\left(\frac{v}{V_0}\right)^2\right] \text{per cent} \quad (5)$$

Figure 2 shows the variation of transmission of an electro-optical shutter as a function of applied potential for several angular orientations of the plane of polarization of the entering light. The analyzer is fixed at α equal to -45 degrees. These curves were plotted using equation 3 which ignores the attenuation of light by the various components of the Kerr cell and does not take into account dispersion in the Kerr effect. The amount of light passed by the shutter increases with the applied potential until the light becomes polarized in the plane of transmission of the analyzer, *A* in Figure 1*c*. At this voltage, the shutter is full-open, but the transmission is fifty per cent because half of the light is rejected by the polarizer *P*. Further increase in voltage causes a decrease in the light transmitted.

From equation 3 and Figure 2 we observe two important conditions for the successful operation of the electro-optical shutter.

1. If there is to be zero transmission when no voltage is applied to the Kerr cell the polarizer and analyzer must be accurately crossed, that is $(\varphi-\alpha)=90°$.
2. The optimum condition of operation is obtained when $\varphi=45°$, see Appendix III.

The first condition is the more critical one, because it affects the completeness of closure of the electro-optical shutter. Fortunately the critical alignment of Polaroids is a simple matter if a photosensitive detector is used to obtain the minimum position. The second condition, namely $\varphi=45$ degrees is not critical. Accuracy within a few degrees can be tolerated. Equation 3 was obtained for operation of the Kerr cell under certain simplified conditions. Because of the attenuation of light by the fluid in the polarizer and the analyzer, and because of dispersion in the Kerr effect, neither full

nor zero transmission actually is attained with increasing voltage applied to the cell.

Components of a Kerr Cell Camera

The components required to make a Kerr-cell camera are shown in Figure 3. Light from the source to be photographed is gathered and rendered parallel by the collimating lens. The polarizer and analyzer are accurately set at an angle of 45 degrees to the electric field and at 90 degrees to one another. For the camera lens and film combination we employed an *f*:4.5 Speed Graphic using 4 by 5 inch film or plate.

Several different polarizing agencies were tried. Nicol prisms, although having an excellent transmission characteristic, are bulky, expensive, and introduce a limited width of field. Polaroid glass is inexpensive, but zero transmission of a crossed pair was difficult to obtain—even with selected pairs. In addition, there were also mounting problems. Best over-all results were obtained with Polaroid J film sheets. This film comes in 12 by 12 inch sheets. It is inexpensive, and our experience has been that suitable uniform sections can be found in any sheet. These sections are easily cut out and properly oriented; they are fastened to the glass cell windows by means of scotch tape. Figure 4 shows the variation of degree of polarization and percentage transmission with wave length for Polaroid J film.[16]

The Kerr Cell Fluid

Among the fluids, nitrobenzene, $C_6H_5NO_2$, seems to have the highest Kerr constant. For this reason, it long has been used as the active substance in Kerr cell work. Commercially known as oil of mirbane, it is a straw-yellow oily liquid with a strong odor of shoe polish. It is very soluble in ether, alcohol, or benzene, but not in water. Nitrobenzene vapor is quite toxic, and the liquid can be absorbed by the body through the skin, causing blood poisoning. Care in handling is consequently essential.

The dielectric constant of nitrobenzene at 20 degrees centigrade is 36. The variation of the dielectric constant of nitrobenzene with frequency is given in Figure 5.[17] As shown, the dielectric constant decreases from 36 at three megacycles per second to 22 at 10 megacycles per second, and continues at the latter value up to 13 megacycles per second. Further data are not available. This would seem to indicate the existence of a first-order Kerr effect at frequencies at least as high as 10 megacycles per second. Experimental observations bear this out, as no time lag in the Kerr effect for pure nitrobenzene has been detected up to nearly 10^{-9} second.[18,19,20] Theory indicates that the relaxation time due to orientation should be of the order of 10^{-9} second.[21]

The absolute spectral transmission for a one centimeter path in very pure nitrobenzene resistivity of the order of 10^{10} ohm-centimeters, is given according to our measurements in Figure 6. The transmission cuts off almost completely at 4,200 Angstrom units.

There are other facts concerning nitrobenzene which are of interest. The refractive index is approximately 1.553. The dielectric strength of commercial oil of mirbane is about 45,000 volts per centimeter and its resistivity is of the order of 10^6 ohm-centimeters. When the liquid is purified, the dielectric strength may be increased to 150,000 volts per centimeter and its resistivity brought up to 10^{10} ohm-centimeters.[22] Under conditions of pulsed voltage, nitrobenzene undoubtedly will withstand much higher electrical stresses although no data have been found for such conditions. However, it has been reported that carbon

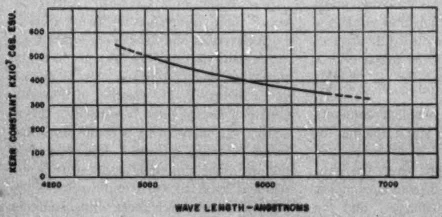

Figure 7. Dispersion in the Kerr constant for nitrobenzene

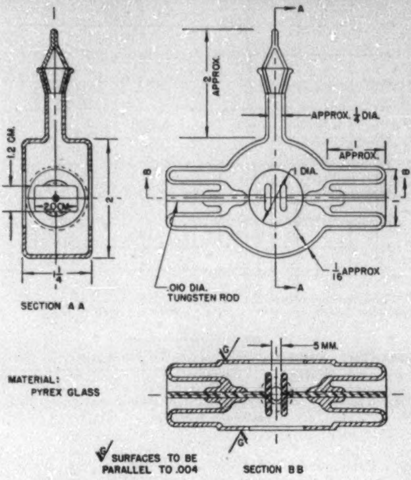

Figure 8 (above). Kerr-cell body

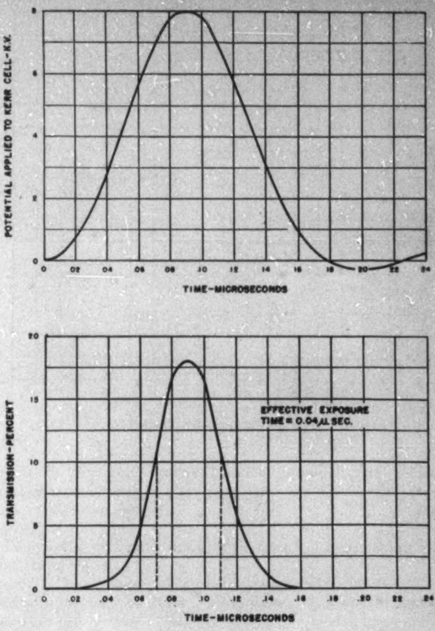

Figure 9 (right)

(a) Voltage applied to Kerr-cell terminals
(b) Kerr cell transmission for voltage pulse of (a) showing effective exposure time of 0.000,000,04 second

disulfide will withstand a gradient of 10^6 volts per centimeter for periods of the order of 10^{-7} second.

The Kerr constant for nitrobenzene as determined by electrostatic methods has been shown to be directly related to its purity as indicated by its resistivity. For this reason, elaborate precautions are usually made to obtain the highest possible purity and resistivity. Because nitrobenzene is a powerful solvent, great care is exercised in the cleansing and handling operations encountered in the construction of Kerr cells.[23] It should be noted here that the operation of a Kerr cell with voltage pulses of very brief duration (10^{-7} second) may not require nitrobenzene of the very highest degree of purity. This matter has not been fully investigated yet.

Figure 7 illustrates dispersion in the Kerr constant for nitrobenzene.[24]

The Kerr Cell Body

The heart of an electro-optical shutter is its Kerr cell unit. Figure 8 shows the structural details of a satisfactory model made of pyrex glass.[18,23] It is one of several designs used in our ultra high-speed photographic work. Circular openings are provided as shown, with suitably large areas about these openings ground flat to facilitate the attachment of the cell windows. These windows are directly in the optical path of the cell and consequently they must be strain free and optically flat enough to insure good photographic definition in the images formed by the associated lens system. Since polarized light is used with the cell, it is obvious that, if the windows are not strain free, they will produce alteration of the state of polarization. Poor operation of the light valve will result. The degree of optical flatness of the cell windows depends upon the use for which the camera is intended. Because the refractive index of nitrobenzene is much closer to that of glass than that of air, the tolerance on flatness for the inside surfaces of the windows can be as much as ten times greater than that for the outside surfaces.

The cell windows are usually completely masked excepting for a small opening for the passage of light. This serves two purposes: reflected light from the electrode faces is prevented from causing extraneous photographic images; and the useful light beam area is limited to a region of comparatively uniform electric field in the cell.

In the earlier models the glass windows were attached to the cell body with ceresin wax as a cement. Later, experimental cell models with fused windows were satisfactorily constructed, but those have not yet been used. The electrode plates were made of pure nickel, silver soldered to tungsten stems, which in turn were sealed into the pyrex body. The plates were rounded at the edges in order to minimize electrical stresses and the consequent possibility of breakdown.

Design Considerations

The design of a Kerr-cell shutter depends upon many factors which involve both electrical and optical considerations. After some thought has been given to the nature of the photographic problem in a given instance, the question of desirable shutter aperture must be settled. A good design will have to be a compromise between certain physical and electrical factors, since the possible aperture is dependent upon the width and spacing of the cell electrodes and these dimensions in

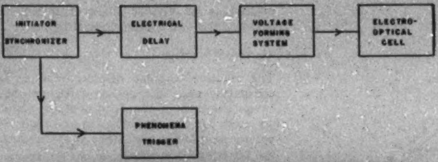

Figure 10. Block diagram of Kerr-cell camera system

Figure 11. Photograph obtained during vaporization of a fine tungsten wire. Taken at 0.60 microsecond after initiation of the electrical discharge

Effective exposure time: 0.000,000,04 second

turn are affected by the length of the electrodes and the availability of electrical means for obtaining and switching voltage to the electrodes. As an example consider equation 4. The condition for full open operation of a shutter is

$$\pi l K E_0^2 = \pi/2 \tag{6}$$

Taking $E_0 = V_0/d$ where d is the separation of the plates, this leads to

$$V_0 = 300d\sqrt{\frac{1}{2lK}} \text{ volts} \tag{7}$$

Since the Kerr constant K at best is of the order of 10^{-6}, shutters of wide aperture will require very high voltages. The alternative of increasing the length of the plates adversely affects the angular field and limits the rapidity with which the shutter can be operated by increasing the electrostatic capacitance of the cell. The Kerr cell shown in Figure 8 is full open with approximately 12,000 volts applied to the cell electrodes. Reference to Figure 2 will show that the most effective utilization of equipment will be obtained if the applied voltage is 80 to 90 per cent of the full-open voltage.

Voltage Forming System for a Kerr-cell Shutter

Up to this point we have discussed the Kerr-cell shutter alone and have given little attention to the electrical requirements which are necessary for its successful operation. To convert the device described to a useful instrument, it is necessary to be able to apply voltage pulses of suitable magnitude and duration to the Kerr cell at accurately predetermined instants. The general problem is too broad to be discussed here. It is sufficient to remark that a large variety of techniques are applicable, and that many elaborate control methods similar to those recently developed for radar may be adapted to this specific use. From the abundance of methods utilizing these techniques, one may choose those systems which best meet specific requirements of accuracy, stability, and simplicity. Since versatility in operation is a characteristic of most electronic control means, it will be found that a wide range of applications will be served by a single apparatus. For example, adjustments of the duration and magnitude of the voltage applied to the cell electrodes can be utilized to vary the effective exposure time over a wide range, and control of the instant of operation of the shutter allows selective photographic studies to be made.

The voltage forming system which was selected for use in obtaining photographic records of the various stages during the sudden electrical vaporization of fine wires provided an effective exposure time of 0.000,000,04 second when used with the Kerr cell shown in Figure 8. In operation, an accurately controlled initiating signal determines the instant at which the voltage pulse shown in Figure 9(a) is applied to the Kerr cell electrodes. This pulse reaches a magnitude of 8 kv and has a duration of 0.18 microsecond. All statements concerning timing have been checked experimentally with the aid of a high-speed oscillograph having a resolution time of 0.002 microsecond. The transmission of the shutter as a function of time, as shown in Figure 9(b), is obtained with the aid of Figure 2 or equation 5. Assuming 64 per cent as an average transmission for each polarizer, the over-all transmission of the shutter, including absorption by the polarizers, can be obtained by multiplying the ordinates of Figure 9(b) by 0.41. Seventy per cent of the area under the transmission versus time curve lies between 0.07 microsecond and 0.11 microsecond. The effective exposure time of the shutter is therefore given as 0.04 microsecond. This value has been checked approximately with the aid of a photosensitive detector.

For special problems, where photographic records of very brief exposure time are required, the accuracy with which the instant of maximum transmission for the shutter can be preselected may become an important matter. In general the midpoint of the exposure time will be determined by the electrical control of the voltage-forming system. Using standard pulsing techniques it was found that the initiation of operation of the shutter could be controlled to better than 0.005 microsecond.

Photographic Results

The Kerr-cell camera described in preceding paragraphs was used successfully to make complete optical studies during the sudden vaporization of various types of fine wires. These wires were supported in a horizontal position by clamping the ends between phosphor-bronze contactors. Vaporization was accomplished electrically by the controlled discharge of a capacitor. Other miscellaneous electrical discharges have also been studied and it is planned to present the results of these tests in a later paper.

The sequence of operations employed in our optical studies is shown in the block diagram of Figure 10. A passive network was used to obtain adjustable delay. By changing the amount of electrical delay, whole series of photographic records for various types of electric discharges were obtained at intervals as small as 0.025 microsecond after the discharge voltage was applied to the electrodes. One photograph was obtained during each discharge.

Figure 11 is a photograph taken at 0.60 microsecond after the application of voltage to a short length of tungsten wire. The effective exposure time was 0.04 microsecond.

Quite clearly the techniques which were employed are applicable, without much change, to other problems.

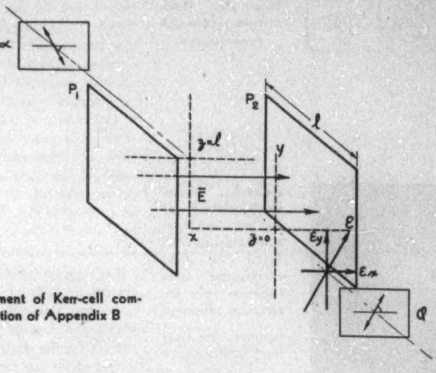

Figure 12. Arrangement of Kerr-cell components using notation of Appendix B

Conclusions

The electro-optical shutter appears to be an excellent instrument for obtaining controlled exposure times of less than 100 microseconds. For photographic studies which require exposure times of less than one microsecond the Kerr cell is almost the only practical solution. Since the inherent time lag in the electrical birefringence of nitrobenzene is of the order of 10^{-9} second, the attainable rapidity of shuttering is limited by the availability of suitable techniques for fast switching of voltage. The ease with which the operation of an "all-electrical" shutter can be synchronized with any phase of phenomena under study, gives these shutters an outstanding advantage over other types.

As an extremely fast photographic shutter, the Kerr cell will be an invaluable research tool in many fields. Among the high-speed self-luminous subjects which it is hoped to study with this device are: many types of electric discharges, the history of arc formation, cathode spot phenomena, the action of fuses, and so on. The instrument will also find applications in the study of certain basic problems in mercury-arc rectification, combustion problems, detonation phenomena, and ballistics. When non-self-luminous objects are to be photographed, the use of a Kerr-cell shutter in conjunction with a synchronous flash lamp makes possible far shorter exposure times than are attainable at present with flash photographic equipment. In addition to these applications, an entire field of "gated optics" optically analogous to radar is opened by use of the electro-optical shutter as a light modulator.

The use of a multiplicity of electro-optical shutters operated in rapid sequence offers a method of obtaining framing rates of many millions per second.

Appendix I

Using equation 1 of the text

$$\frac{n_x-n_y}{\lambda}=KE^2 \tag{8}$$

now

$$n_x=v/v_x$$

and

$$n_y=v/v_y \tag{9}$$

where

v = velocity of light in free space

v_x, v_y = velocity of the components parallel and perpendicular to the applied electric field in the Kerr cell.

Substituting equation 9 in equation 8 we obtain

$$\frac{v}{\lambda}\left(\frac{1}{v_x}-\frac{1}{v_y}\right)=KE^2 \tag{10}$$

Since

$$\nu=v/\lambda=\omega/2\pi$$

Equation 10 becomes

$$\omega\left(\frac{1}{v_x}-\frac{1}{v_y}\right)=2\pi KE^2 \tag{11}$$

Multiplying both sides of equation 11 by the length of the Kerr cell electrodes, l

$$\omega\left(\frac{l}{v_x}-\frac{l}{v_y}\right)=2\pi lKE^2 \tag{12}$$

now let

$t_x=l/v_x$ = time required for the x component of light to traverse the Kerr cell

$t_y=l/v_y$ = time required for the y component of light to traverse the Kerr cell

The difference in transit times may be expressed as an angular phase displacement between the two components of light

$$\omega t_x-\omega t_y=\delta_x-\delta_y=\delta \tag{13}$$

The relative angular displacement δ, is equivalent to a time phase difference between the two components of light which accounts for the alteration in the state of polarization of the total light as it traverses the birefringent medium.

From equation 12

$$\delta=2\pi lKE^2 \tag{14}$$

Appendix II

In Figure 12, P_1 and P_2 are the electrodes in a Kerr cell and $\boldsymbol{E}$ is the electric field applied. The polarizer is oriented at an angle φ with the applied field $\boldsymbol{E}$, and the analyzer is at an angle α as shown. Let $\boldsymbol{e}$ be the plane polarized light vector as it leaves the polarizer. Then using standard vector notation

$$\boldsymbol{e}=\boldsymbol{i}e_x+\boldsymbol{j}e_y \text{ for any } t, z \tag{15}$$

The components of the light vector can be written

$$\begin{aligned} e_x&=[e_0\epsilon^{-j\omega(z/v-t)}]\cos\varphi \text{ real part}\\ e_y&=[e_0\epsilon^{-j\omega(z/v-t)}]\sin\varphi \text{ real part}\end{aligned} \tag{16}$$

where e_0 is the magnitude of the electric vector in the incident light, and v is the velocity of propagation of light in the z direction.

Due to the applied electric field $\boldsymbol{E}$, the components e_x and e_y traverse the Kerr-cell field with velocities v_x and v_y respectively.

Hence

$$\boldsymbol{e}=\boldsymbol{i}e_0\epsilon^{-j\omega(z/v_x-t)}\cos\varphi+\boldsymbol{j}e_0\epsilon^{-j\omega(z/v_y-t)}\times \sin\varphi \text{ real part} \tag{17}$$

Using $v=\lambda\nu$, and taking $z=l$,

$$\begin{aligned} \frac{\omega z}{v_x}&=\frac{2\pi l}{v_x}=\delta_x\\ \frac{\omega z}{v_y}&=\frac{2\pi l}{v_y}=\delta_y\end{aligned} \tag{18}$$

Substituting equations 17 and 18, we get the vector expression for the electric field in the light at the analyzer ($z=l$) at any time t

$$\boldsymbol{e}=\boldsymbol{i}e_0\epsilon^{-j(\delta_x-\omega t)}\cos\varphi+\boldsymbol{j}e_0\epsilon^{-j(\delta_y-\omega t)}\times \sin\varphi \text{ real part} \tag{19}$$

The light which passes through the analyzer, is the component of $\boldsymbol{e}$ in the α direction

$$e_\alpha=\boldsymbol{e}\cdot\alpha_1 \tag{20}$$

where

$$\alpha_1=\boldsymbol{i}\cos\alpha+\boldsymbol{j}\sin\alpha \tag{21}$$

so

$$e_\alpha=e_0\cos\varphi\cos\alpha\epsilon^{-j(\delta_x-\omega t)}+ e_0\sin\varphi\sin\alpha\,\epsilon^{-j((\delta_y-\omega t)} \text{ real part} \tag{22}$$

At any instant, the magnitude of the light vector which passes through the analyzer will be given by the real part of the expression 22.

This equation may also be written in the form

$$e_\alpha = e_1 \epsilon^{-j(\theta - \omega t)} \qquad (23)$$

where e_1 is the maximum amplitude of the harmonically varying light vector $\mathbf{e}_\alpha$.

Since the intensity of the light emerging from the analyzer is proportional to the square of the maximum amplitude of the light vector, we have

$$e_1^2 = |\mathbf{e}_\alpha|^2 = \mathbf{e}_\alpha \mathbf{e}_\alpha^* \qquad (24)$$

where $\mathbf{e}_\alpha^*$ is the complex conjugate of $\mathbf{e}_\alpha$.

$$\mathbf{e}_\alpha^* = e_0 \cos\varphi \cos\alpha \epsilon^{+j(\delta_x - \omega t)} + e_0 \sin\varphi \sin\alpha \epsilon^{+j(\delta_y - \omega t)} \qquad (25)$$

and

$$|\mathbf{e}_\alpha|^2 = e_0^2[\cos^2\varphi \cos^2\alpha + \sin^2\varphi \sin^2\alpha + 2\sin\varphi \sin\alpha \cos\varphi \cos\alpha \cos(\delta_x - \delta_y)] \qquad (26)$$

Now

$$(\delta_x - \delta_y) = \delta$$

as in equation 14, Appendix I, and using the equation

$$\cos\delta = 1 - 2\sin^2 \delta/2$$

we obtain

$$|\mathbf{e}_\alpha|^2 = e_0^2[\cos^2(\varphi - \alpha) - \sin 2\varphi \sin 2\alpha \sin^2\delta/2] \qquad (27)$$

The transmission is defined as the ratio of intensities of emergent and incident light. Thus the percentage transmission is given by

$$T = 100 \frac{|\mathbf{e}_\alpha|^2}{e_0^2} \text{ per cent}$$

So

$${}_\varphi T_\alpha = 100[\cos^2(\varphi - \alpha) - \sin 2\varphi \sin 2\alpha \sin^2\delta/2] \text{ per cent} \qquad (28)$$

Since 50 per cent of the light incident on the first polarizer is rejected by it, we arrive at an expression for the over-all transmission of the Kerr cell unit by dividing equation 28 by two

$${}_\varphi T_\alpha = 50[\cos^2(\varphi - \alpha) - \sin 2\varphi \sin 2\alpha \times \sin^2\delta/2] \text{ per cent} \qquad (29)$$

For

$\varphi = 45$ degrees, $\alpha = -45$ degrees

$${}_{\pi/4}T_{-\pi/4} = 50[\sin^2 \delta/2] \text{ per cent} \qquad (30)$$

Using equation 14, Appendix I

$${}_{\pi/4}T_{-\pi/4} = 50[\sin^2(\pi lKE^2)] \text{ per cent} \qquad (31)$$

If the electric field for full-open operation is E_0 corresponding to an applied potential of V_0, the transmission at any applied potential, v, is

$${}_{\pi/4}T_{-\pi/4} = 50[\sin^2(\pi lKE^2)] \text{ per cent} \qquad (32)$$

$$= 50\left[\sin^2 \frac{\pi}{2}\left(\frac{v}{V_0}\right)^2\right] \text{ per cent}$$

Appendix III

The angular orientation of the "crossed" polarizers in order to allow maximum transmission for the Kerr cell may be obtained from equation 29 of Appendix II. Assuming perfectly "crossed" polarizers $(\varphi - \alpha) = 90$ degrees equation 29 becomes

$${}_\varphi T_\alpha = -50[\sin 2\varphi \sin 2\alpha \sin^2 \delta/2] \qquad (33)$$

$$= -50[\sin 2\varphi \sin 2(\varphi - 90°) \sin^2 \delta/2]$$

$${}_\varphi T_\alpha = 50[\sin^2 2\varphi \sin^2 \delta/2] \qquad (34)$$

$$\frac{\partial_\varphi T_\alpha}{\partial\varphi} = 200 \sin 2\varphi \cos 2\varphi \sin^2 \delta/2$$

To determine the maxima, equation 34 is set equal to zero yielding two solutions

$$\cos 2\varphi = 0$$

$$2\varphi = \pi/2,\ 3\pi/2, \text{ and so forth} \qquad (35)$$

$$\sin 2\varphi = 0$$

$$2\varphi = 0,\ \pi, \text{ and so forth} \qquad (36)$$

The values of φ given by equation 36 result in minimum or zero transmission. For maximum transmission the condition described in equation 35 will apply. Therefore

$\varphi = \pi/4,\ 3\pi/4$, and so forth

are positions of the polarizer for which transmission will be optimum.

The analyzer angle is found from the relation $(\varphi - \alpha) = \pi/2$

A specific example is

$\varphi = 45$ degrees, $\alpha = -45$ degrees

Synopsis: The paper describes a new multiplexing system employing time division. The system features pulse amplitude modulation with a filtering arrangement for minimizing the required transmission bandwidth. The distortion and crosstalk requirements for commercial applications are met over transmission paths including radio relay repeaters. A discussion of the channelizing, synchronizing, transmission equipment, and system performance data is included.

ELECTRICAL engineers working in the communications field are concerned with transmission systems for carrying messages over long distances with maximum fidelity. Usually such systems have terminal equipment for multiplexing many narrow band channels into a single wider band channel before transmission is started. Terminal equipments usually are divided into two groups according to their method of multiplexing. The frequency division group has been used widely,[1,2] and there have been many recent developments in the time division groups.[3,4] However, the time division systems previously described have required a transmission bandwidth many times greater than the bandwidth of the original total intelligence. Because of this, time division terminal equipments heretofore have been applicable only to radio relay systems employing pulse modulation. The terminal equipment described in this paper utilizes time division multiplexing but is characterized by requiring a transmission bandwidth approximating that of the original total intelligence. This low transmission bandwidth requirement makes the terminal equipment adaptable for use with either amplitude or frequency modulated transmission systems. The techniques to be described are applicable to amplitude modulated pulse multiplexing systems. The system described uses linear amplitude modulation but pulse-code modulation systems may be considered as a particular example to which these same techniques also may be applied.

As the art of radio relaying at microwave frequencies has advanced, the engineering problems inherent in the art have been defined more clearly. The direction of one solution to these problems is the use of a low bandwidth time division terminal equipment in association with a relay system using a frequency modulated carrier. If the required transmission bandwidth is sufficiently low the relay system may use either subcarrier modulation[5] or direct modulation with heterodyne remodulation.[6] With these transmission problems in mind the specific requirements for a multiplex terminal equipment which would function most effectively with a radio relay or coaxial cable transmission system were given attention. Out of this work has come the multiplexing system to be described.

General Description

The equipment is a time division system. The usual sending terminal has multiple band inputs, timing generator, sampling gates, and the combining stages from which the sending terminal output is derived. Amplitude modulated signals are handled throughout this equipment. Figure 1 is a block diagram of the sending terminal.

A carrier oscillator with a 60-kc sinusoidal output is used to trigger an 8-kc pulse generator. This is accomplished by frequency doubling and counting circuits together with gate circuits to insure uniform timing intervals. The pulse generator is arranged to have a generally triangular pulse output. The delay line distributor is a lumped constant transmission line or low pass filter made up of "M" derived sections such that its total time delay is 125 microseconds equally divided into 30 intervals of 4.16 microseconds. This line has a characteristic impedance of 2,500 ohms and a bandwidth of approximately 300 kc. The pulse generator output is applied to the line and the combination provides a traveling delay line signal which may be used to successively gate 30 band modulators at an 8-kc rate. The band modulators may have a voice band signal, or other signal with a frequency range of 60 to 3,300 cycles, applied to their inputs. The output of any individual modulator will be a pulse signal similar in shape to the delay line pulse signal but modulated in amplitude in accordance with the input signal amplitude at the time of application of the delay line signal. The time-spaced outputs of all of the modulators are combined into a pulse train, as shown at output terminal A. In order properly to index the receiver, one band modulator is modified to have two input terminals. One input is normally a 3,900-cycle indexing tone supplied from a suitable oscillator and the other input may be a voice band or order-band input having a frequency range of 60 to 2,500 cycles.

In conventional pulse amplitude modulation systems, output at A would be recognized as the normal sending-terminal output signal. It could be applied to any transmission medium having suitable passband characteristics. In the case of a microwave radio relay system, the signal could be used to frequency modulate the carrier or subcarrier of the radio relay. The output signal of the transmission medium should be a replica of the input signal ready for application to the receiving-terminal equipment.

The receiving-terminal equipment also follows the general pattern of similar time division systems. If the signal from output terminal A is applied to the receiving-terminal input it is necessary that we first

produce and maintain proper registration or indexing of the voice bands, and second, demodulate the voice bands. Indexing and synchronizing are accomplished as two separate steps. The indexing problem is solved by the modulation of one of the bands by a tone slightly above the normal voice band passband such that the particular band is characterized by an unusual constant-tone modulation. The receiving terminal then is equipped with a single band having a means for recognizing this tone and indexing thereon. Until indexing is accomplished, the synchronizing circuits are disabled and the receiving-terminal timing generator repetition rate is made slightly different than the sending-terminal timing generator repetition rate so that slippage occurs between the received band pulses and the receiving-terminal gating pulses. When the proper channels are in register, the slip circuits are disabled and the receiver-terminal timing generator then is driven by the synchronizing circuits operating on the received signal. Synchronizing is accomplished by the transmission of band repetition rate frequency components in the sending-terminal signal. The signal energy of this frequency, called the carrier, is separated from the composite signal and, after amplification, may be used to control the timing generator in the receiving terminal. In order to index the receiving terminal, a slip-frequency oscillator is used as shown in Figure 2. The oscillator is crystal controlled to a frequency approximately 30 cycles higher or lower than the 240-kc carrier frequency of the sending terminal. During the indexing period, this slip frequency signal is applied to counter circuits and the timing generator to produce a delay line pulse as in the sending terminal, except that the repetition rate of this pulse is slightly slower or faster than the sending terminal pulse rate. Accordingly, there is a gradual drift of the receiver input signal with respect to the delay line keying signal. During each cycle of the slip frequency, a time of one-thirtieth of a second in this case, the bands drift into proper registration. During this brief interval of proper registration, the input signal is applied to the band separators as will be described. The presence of the indexing signal in its assigned band indicates proper register of the band pulses and the receiving-terminal separators, and this signal energy may be used therefore to operate a changeover circuit. This circuit, during the indexing interval, has connected the slip frequency oscillator to the timing generator. Once the bands have been indexed, the circuit discards the slip frequency oscillator and connects the derived sending-terminal carrier signal to the timing generator, thus locking the receiving-terminal gating rate to the sending-terminal sampling rate.

Proper indexing is insured by the deliberate modulation of one voice band with a tone which is higher in frequency (3,900 cycles) than the signals permitted in any other voice band, and by the provision in the corresponding voice band at the receiving terminal of a sharp bandpass filter responsive to this tone.

This indexing circuit has been given rigorous tests and has been found to index in less than one-thirtieth of a second following a signal interruption and to hold the receiving terminal in proper register with received signal-to-noise ratios as low as 0 decibel.

Voice-band demodulation is obtained by the progressive gating of pulse separators with subsequent filtering and am-

plification of the modulation energy of the band pulse spectrum. The gating is derived from the delay-line distributor as explained.

The foregoing general description of the terminal equipment indicates one system whereby the basic functions of band multiplexing, indexing, and synchronizing may be performed. If an adequate transmission system were interposed between the sending and receiving terminals the desired band output signals could be obtained.

Modulator and Demodulator Circuits

Several specific circuits within the system described are worthy of more detailed description. The sending-terminal modulator and receiving-terminal demodulator are very important since, to a major extent, they determine the distortion and crosstalk levels within the system.

The modulator schematic for a single band is shown in Figure 3. The principal tube is a miniature pentode type *6AS6*. The triode section is operated class A with a prescribed amount of cathode degeneration. Voice band input at a rated level of +13 decibels (referred to one milliwatt in 600 ohms) is coupled to the control grid, g_1. The delay line pulse, obtained at the successive taps, is scaled by resistors R_1 and R_2 to the values shown and applied to the suppressor grid, g_3. This grid is normally so biased as to cut off the plate current except during the suppressor gating interval. In view of the relatively large cathode voltage swing (approximately four volts peak-to-peak) the suppressor is a-c coupled to the cathode so that the audio signal appears at *B*. R_1 and R_2 are relatively high value resistors to permit this. When the delay line pulse is applied, the high back resistance of the *6AL5* diode prevents loading of the circuit by the low cathode circuit impedance. The plate of the tube is connected in parallel with a group of plates of similar stages to a common plate load, and a pulse of approximately 2-volts peak amplitude, modulated ±0.7 volt, is derived from the plate circuit. The time-staggered outputs of this and other modulator stages are thus combined into a pulse train which is coupled through an amplifier or other combining stage to the terminal output *A*. A specific virtue of this modulator circuit, in addition to its exceptional amplitude linearity, is found in the fact that the energy distribution in the spectrum of the output pulse train is not affected by modulation. This makes possible the application of circuits to restrict the required transmission bandwidth as will be described.

The demodulator circuits in the receiving terminal convert this pulse signal into its many original voice band signals. Several circuit arrangements have been successfully used as demodulators. They vary considerably in the degree of complexity and in performance. The circuit of Figure 4 is representative and has adequate performance with reasonable simplicity.

The amplified pulse signal from the sending terminal is applied to the grid of the *6AS6* pentode, the cathode, grid, and screen of which are operated class A. The gating signal obtained from the timing generator through the delay line distributor cuts off the *6J6* triode unit and allows its plate and the *6AS6* suppressor, which have been residing at a negative voltage greater than suppressor cutoff, to rise. The suppressor rise is arrested by conduction of the crystal diode, thus holding the supressor at cathode potential. Since the latter moves with the control grid signal, the gating pulse is therefore superimposed on the modulation present on the band pulse and distortion due to curvature of the suppressor characteristic is eliminated. The plate current pulse is a true reproduction of the incoming signal during the interval allocated to that one band. If the plate circuit has sufficient bandwidth, then the charge drained from the storage capacitor *C*, via one half of the *6AL5* diode and the coupling capacitor will be proportional to the peak current in the tube. This charge is then trapped on the capacitor, since the diode cuts off as the plate swings positive with the signal, and all other leaks are purposely made high. The charge conditions on the coupling capacitor are restored by the other half of the *6AL5*.

The charge and hence the voltage across capacitor *C* remains substantially unchanged for a time interval of 120.8 microseconds. A new pulse from the timing generator coming down the delay line distributor encounters the discharge double triode *12AT7* 4.16 microseconds ahead of the *6J6* gating triode. The grid of the second section rises with the plate of the first as the latter is cut off; in so doing it passes cutoff and allows current to flow into the capacitor *C*. The *6AL5* diodes prevent a charge accumulation which would raise the potential on *C* appreciably positive by bypassing the current from the *12AT7* to ground. The output from the separator and storage circuit is the potential across *C* and this voltage when properly filtered may be considered as the demodulated output of the band. It is only necessary to provide suitable voice band amplification and impedance transformation to restore the original character of the voice band input to the multiplex output terminals.

The modulator and demodulator circuits as described have proved very satisfactory for the experimental work to date. Of course, simpler circuits with even better performance will be developed as the work progresses.

The Sending Terminal Output Signal

When one has terminal equipment of the type just described, or its equal, the problem of a transmission medium becomes most important. In our considerations we have been restricted primarily to the use of microwave radio relay systems and our study has concentrated on the known faults of such systems. Since

all types of radio relays cannot be considered in this brief paper; we shall consider the relay system which appears to be superior. Such a relay uses frequency modulation of the carrier and either a heterodyne type repeater, as has been previously described, or a locked oscillator type of repeater which will be described in a forthcoming paper. With a wide-band relay of this type it is possible easily to maintain good signal-to-noise ratios at reasonable modulation bandwidths but on account of the wide carrier frequency deviations used, the amplitude linearity of the system is not exceptional unless elaborate precautions are taken. These two primary factors, along with minor features, indicated that a time division multiplex system would match such a relay system best. With time division, only the signal of one channel is ordinarily present at any instant, hence the amplitude linearity and signal-to-noise ratio of the relay system need only be that required by the requirements of any single voice band. Harmonic distortion does not cause beat notes or noise in other bands. Further, distortions of the relay output signal due to multipath or other propagation or transmission defects will not be observed except as for their effect on each voice band individually.

Observing the advantages of time division multiplexing from the point of view of the radio relay requirements, we were disturbed by its one largest disadvantage; namely, that a modulated pulse train such as indicated at output terminal A of Figure 1 obviously required a bandwidth far in excess of the bandwidth of the intelligence being transmitted. In fact, for 30 voice bands representing approximately 100 kc of intelligence (neglecting guardbands) a low-pass bandwidth of approximately one megacycle would be required to satisfactorily resolve the sending-terminal output pulse train. Work on this phase of the project has progressed successfully and a technique has been developed whereby the required transmission bandwidth is comparable to the total input intelligence bandwidth by virtue of a coding arrangement using amplitude division. That is, the signal amplitude is shared among a few channels in a fixed proportion determined by the sending terminal equipment.

The apparatus for minimizing the required bandwidth is shown as the filter assembly on the output of Figure 1 and the corrector assembly at the input of Figure 2.

The filter assembly of Figure 1 performs the function of limiting the high frequency end of the spectrum of the signal from the sending terminal; thus the transmission equipment is called upon to handle a narrower band of frequencies than would be required otherwise. That this filtering function can be performed without distorting the modulation information in each voice band is evident from the Fourier analysis of the pulse train. Assuming a pulse train subject only to pure amplitude modulation (with no distortion of the pulse shape), this analysis shows the spectrum of the pulse train to be a fundamental frequency, corresponding to the basic sampling rate (8 kc) and its harmonics, each having an upper and a lower sideband produced by modulation. Thus modulation of one band will produce a spectrum of energy including the original modulation spectrum plus the band sampling rate and its harmonics, each of the latter having an upper and lower sideband. To discard some of the high frequency energy of this composite spectrum without distortion of the modulation information, it is required that the distribution of energy among the sampling frequency and its harmonics be a constant when the pulse train is modulated. This can be accomplished only with a modulator which is free of all modulations (width, shape, and so forth) other than amplitude. The modulator of Figure 3 is such a modulator, and no measurable increase in distortion occurs whether the sending terminal output is unfiltered or filtered.

If the foregoing requirements are met, the result of proper low pass filtering may be summed up as a failure to define the original pulse train. Therefore, a single band pulse is widened so as to overlap one or more adjacent band pulse intervals. The degree of this effect depends on how severely the bandwidth is curtailed and upon the transient response of the filter. This broadening of the pulse width by filtering, and its consequent overlap in time with the signal pulse of another band, results in a sharing of the total signal voltage from the sending terminal among a number of channels, and in the need for a compensating unit at the receiving terminal.

The extent of the basic pulse broadening is calculable from a statement of the

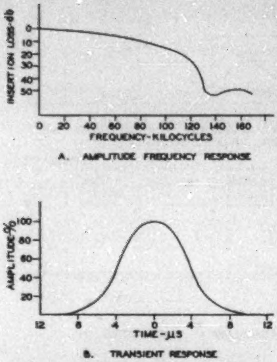

Figure 8. Typical filter characteristics

transient response of the filter. A filter with a symmetrical transient response approximating an error function shape $(f_t = e^{-a^2t^2})$ has been used for most applications. The typical responses of one such filter are shown in Figure 5*A* and 5*B* along with a calculated output pulse spread showing, in Figure 5*C*, corresponding interference in adjacent channels. In other applications a filter having a nonsymmetrical transient response possesses some advantage. Once a set of characteristics have been settled upon, the construction of the filter may be undertaken. It must be understood that since we are dealing with pulses, we are most interested in the transient response of the filter and not in its amplitude or phase response alone.

One actual filter unit used to accomplish this reduction in bandwidth is a low pass network of the constant resistance bridged-*T* variety,[7] successive sections of the composite network not necessarily being identical. A statement of the general characteristics which such a network ought to possess may clarify the design problem. Having specified a cutoff frequency at which the output shall be more than 40 decibels below the input, the variation of the transmission characteristics of the network for frequencies up to this limit are of concern. Certain responses are more desirable than others inasmuch as they make the compensation problem at the receiving terminal less complicated. A filter network whose characteristic transient is symmetrical and whose damping factor is just sufficient to prevent overshoots will provide, in general, a minimum of interference with adjacent bands.[8] The transmission characteristics of a network having such a characteristic are that the amplitude frequency response is a gradual slope throughout the pass band, while the phase frequency response is zero at zero frequency and increases linearly until after amplitude cutoff is reached. These responses are indicated in Figure 5*A* and 5*B* and serve to define network performance. The filter network chosen approaches these ideals quite closely with reasonably few parts and critical adjustments. The general form of one section of the network is shown schematically in Figure 5*D*. In cases where a nonsymmetrical transient response is desired, it has been found most expedient to obtain such responses by adding to the filter a required pattern of phase-equalizing circuits which are used to obtain the desired response without modifying the filter amplitude response.

In summary, the sending-terminal output is a pulse train which has been so filtered as to narrow the frequency spectrum of the signal energy while permitting a division of the instantaneous amplitude of the output signal among adjacent channels. Of course, from the filter characteristics, the amount of signal energy due to each channel is known, and, at the receiver, use is made of this information.

During field testing of this system of multiplexing using radio relays as the transmission medium, it was verified that, if desired, a relay system with a poor transient response might be used with this pulse system by accounting for the change in pulse shape introduced by the relay when making the initial receiving-terminal setup adjustments. This is of great importance in any practical radio relay network.

In preceding paragraphs it was noted that synchronization of the receiving terminal was obtained by the recovery of the carrier frequency. When a filter of the foregoing type is used it will be recognized that the normal carrier frequency, which is the 240-kc signal, is fully attenuated. The requirement for a carrier frequency signal at the receiving terminal is met therefore by the addition to the filtered output pulse train of a subcarrier which is at a frequency within the filter transmission band. There are two groups of choices for this subcarrier frequency: it may be a harmonic of the band sampling rate, or it may be midway between such harmonics. In the first, the receiving terminal input signal will show different voltage levels for successive signal bands but will not produce any undesired modulation signals. In the latter, each voice band will be modulated at a 4-kc rate due to the nonintegral relation of a subcarrier and sampling rate but such 4-kc signals may be rejected by the modulation recovery device. Either system is usable and a subcarrier at 60 kc is shown in Figure 1. The amplitude of the added subcarrier is controllable and a level of less than 10 per cent of the peak signal has been found in practice to be more than adequate.

It now remains to add the subcarrier frequency to the output of the filter and the signal output of the sending terminal is complete. Derived from the crystal controlled oscillator as shown in Figure 1, the subcarrier frequency is run through a band-pass filter of conventional design to eliminate undesired harmonics, phased to an advantageous position with respect to the composite output, and added thereto.

The Receiving Terminal Corrector Circuits

It is one of the design aims of the receiving-terminal common-band equipment to remove the mutual interference between channels, which interference was controllably introduced in the sending terminal, as completely as possible. At the same time, the equipment to accomplish this should remain simple, easy to adjust, and stable with time. The operation of the compensation system employed is based upon knowledge of the relative amplitude of the output of the sending terminal at time intervals corresponding to adjacent bands on either side of the interfering band, in terms of the output of the interfering band. In other words, for any band combination in which mutual interference results it always is known that the interference of one band on another is a fixed per cent of the peak of the interfering signal amplitude, the percentages of interference being specified by the filter transient response.

Figure 6 shows in some detail the results of filtering a typical multiband amplitude-modulation pulse train by a symmetrical transient filter. Figure 6*A* is an idealized section of the pulse train from the sending-terminal multiplex before filtering, with six of the band pulses present in the portion shown. If a band circuit is modulated, the modulation may vary the pulse amplitude between the limits shown crosshatched, and the crosstalk in adjacent bands will be known from the filter characteristics. As an example, the filter characteristics have been chosen to give adjacent-channel crosstalk only. Figure 6*B*, therefore, shows the component contributions of each band and the resultant output at the filter output terminals. In order to make clear the fact that the receiving-terminal channel detectors respond only to the peak of the modulation spread produced by the filtering action, it is emphasized that gated peak detectors are used, timed by the carrier transmitted with the multiplex signal. Interference of band N with bands $N-1$ and $N+1$ is readily visible. Figure 6*C* shows the effective gating function which the receiving terminal detectors exhibit. At the times labeled $N-1$ and $N+1$, corresponding to the opening of the band circuit separators, it is apparent that some signal from band N will be present also. It is the purpose of this discussion to show how this interference may be eliminated. The interference, however, will be corrected to zero only at the indicated gating instants. Basically, the corrector operates to cause the signal of any band to be zero at all times spaced by the band interval from the peak of the band modulation; that is, interference will be zero at the gating intervals of all other bands. Figure 6*D* illustrates a typical corrector output for the input signal of Figure 6*B*. It will be observed that the resultant signal amplitude is zero at the gating time of all bands other than the originally modulated band. Thus band interference has been eliminated. The block diagram for a corrector network which might be used to eliminate the interference shown by Figure 6*B* is shown in Figure 7*B*. It may consist of a series of delay networks driven from one end, with each delay unit having a time delay equal to the band interval. From the junctions of these networks, signals are fed through unilateral attenuators and polarity inverters, as required. They then are added to produce an output voltage which is used to energize the band separators. Proper adjustment of the attenuators permits the use of the signal of any band to cancel its own interference with all other bands. The operation may be visualized as follows: As the signal of any band passes through the delay network, the total output of the network is equal to the amplitude of the signal at that time, as shown in Figure 7*A*, multiplied by the corresponding attenuator gain. These outputs are shown in Table I for successive band gating intervals. By equating the outputs to zero at the adjacent band intervals the settings for the attentuators are calculable. Attenuator settings are also readily found experimentally when the equipment is initially adjusted. For correction of interference to absolute zero at all times, an infinite number of delay networks and attenuators would be required. However, the cancellation process can be made to converge rapidly for many useful transient responses such that, in practice, for as much as 30 per cent interference in adjacent channels, only six networks are required to reduce the crosstalk in all bands to negligible values. As an illustration, Table I indicates a residual output at channel $(N+3)$ and $(N-3)$ gating times. This ordinarily will be a negligible value, but it may be reduced as far as desired by the addition of more corrector networks.

The final practical limit to which this bandwidth reduction system can be extended has not yet been determined. A second paper to be published in the near future will treat the various criteria for satisfactory operation. To date, however, the 30-channel 240-kc pulse train system described has been operated successfully through a filter system having the amplitude characteristic of Figure 8*A* and a transient response of Figure 8*B* with a 10-section corrector reducing all crosstalk to 45 decibels below the output signal level. If the frequency scale of Figure 8*A* is multiplied by a factor of 1.15, a 6-section corrector will reduce the crosstalk level to 60 decibels below the output signal level.

Conclusions

It has been interesting to study the transmission characteristics of the sending-terminal filter assembly and the receiving-terminal corrector assembly when connected in series, and to consider their effect as a transmission medium on the signal to noise ratio of the signal. These calculations and equipment tests verify the conclusion that the bandwidth of a transmission system for use with the filter described by Figure 8*A* need not exceed 120 kc. Since the corrector adjustments have been found in practice to be stable and easy to adjust, the use of the techniques described makes possible the transmission of time-division multiplexed signals over a low bandwidth cable or over a radio relay system employing frequency modulation of the carrier. The high modulation index now possible with frequency modulation transmission systems results in favorable output signal-to-noise ratios.

From these characteristics it will be clear that no signal energy at frequencies above approximately 120 kc is required for the transmission of the complete signal. This compares favorably with the requirements for single-sideband amplitude modulation transmission, yet retains the features of pulse transmission. Of course, since the system is a pulse system, attention must be paid to the phase response throughout the entire pass band. It also will be understood that a low pass filter ordinarily is used ahead of the receiving-terminal input to eliminate any high-frequency noise which may have been added to the signal by the transmission system. This filter need be only slightly wider than the filter at the sending terminal, in order for its effect on the system transient response to be negligible. The amount of transmission loss inserted at frequencies above 120 kc makes no difference in the system operation. During field tests in June, 1948, the cooperation of the Western Union Telegraph Company in making available its radio relay circuits and its multiplexed telegraph voice band load signals, made possible a comprehensive testing program. From these tests the principles of operation were confirmed and new designs accommodating a greater number of voice bands are now in progress.

Table I. Output Voltage

Time	Output
N	$bA_2+aA_3+cA_4$ = desired signal
$N-1$	$bA_1+aA_2+cA_3=0$
$N+1$	$bA_3+aA_4+cA_5=0$
$N-2$	aA_1+cA_2 $=0$
$N+2$	bA_4+aA_5 $=0$
$N-3$	cA_1 = residual interference
$N+3$	bA_5 = residual interference
$N-4$	0
$N+4$	0

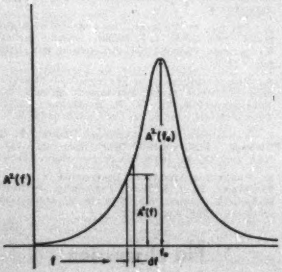
The Distinction Between Effective and Circuit Bandwidths

WILLIAM J. KESSLER
NONMEMBER AIEE

IN recent years, the term bandwidth has appeared so frequently that it appears desirable to discuss briefly the two major interpretations associated with this term. It is the primary purpose of this paper to cast into sharp relief the significant differences between the meaning of circuit bandwidth, which is employed to specify the frequency discriminating properties of networks; and the effective bandwidth, employed to specify the noise transmission properties of passive networks.

Despite the fact that electrical networks may display the same maximum sensitivity and the same selectivity, according to the standard definition, they will nevertheless display different sensitivities to noise. It is evident, therefore, that the results of noise measurements are meaningless unless accompanied by more adequate frequency response data of the measuring instruments reduced to a common basis. The concept of effective bandwidth, suitably defined, satisfies this requirement. The term "circuit bandwidth" is then reserved to specify the selectivity or frequency discriminating properties of any given network.

Figure 1. Squared response curve of physical network



Definitions

Circuit bandwidth, usually represented by Δf, may be defined as the difference between the two frequencies at which the response is below the maximum a specified degree. When the specified attenuation is three decibels, these two frequencies are often referred to as the "half power" points. The definition for effective bandwidth B, however, is slightly more complex, since it is a measure of the network response to noise or other transient phenomena whose components are distributed throughout the frequency spectrum. For this reason, effective bandwidth is often referred to as the "noise" bandwidth. The effective bandwidth of any network of maximum response $A(f_o)$ is, therefore, defined as being numerically equal to the bandwidth of an equivalent network whose response is $A(f_o)$ throughout its entire transmission band, provided the noise powers developed across the output terminals of the two networks are equal for the same noise signal input.

Actually, the determination of the effective bandwidth of a network reduces to the problem of finding an equivalent rectangular response curve for the physical network. It is recognized readily that for the rectangular response curve there is little question as to the interpretation of bandwidth regardless of how arbitrary the definition might be in terms of relative response.

Theoretical Considerations

Response curves are, in general, graphical representations of voltage ratios as a function of frequency, which are in turn proportional to the square root of the power ratios. Since the average time rate of change of electric energy across the output terminals is proportional to the square of the voltage, Figure 1, it is possible to write the following differential equation

$$dP=\phi(f)A\ (f)df \tag{1}$$

where dP is the noise power contribution at each frequency and $\phi(f)$ is the energy-frequency distribution of the noise under consideration. Applying equation 1 to the physical and equivalent "rectangular" network exemplified in Figures 1 and 2, integrating over appropriate limits and under the conditions of the definition equating the two expressions, yields

$$\int_{f_o-B/2}^{f_o+B/2}\phi(f)A^2(f_o)df=\int_0^\infty \phi(f)A^2(f)df \tag{2}$$

Inspection of equation 2 discloses that further analytical progress is impossible unless the distribution of the noise is specified. Assuming the simplest possible

WILLIAM J. KESSLER is with the engineering and industrial experiment station, University of Florida, Gainesville, Fla.

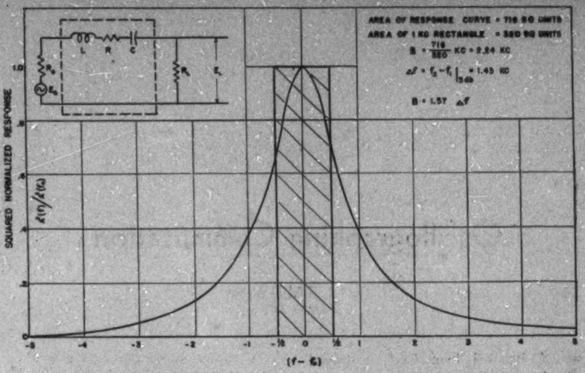

Figure 3. Squared response curve of physical network and 1-kc reference rectangle

distribution, one that is uniform and continuous such as "White" noise and approximated closely by random noise, equation 2 reduces to

$$KA^2(f_o)B = K\int_0^\infty A^2(f)df \tag{3}$$

where K is the constant form of $\phi(f)$ and evidently divides out. Thus the effective bandwidth B becomes

$$B = \frac{\int_0^\infty A^2(f)df}{A^2(f_o)} \tag{4}$$

Equation 4 shows that the effective bandwidth for any network is equal simply to the area under the squared response curve divided by the square of the maximum response.

Determination of Effective Bandwidth

The area under the squared response curve plotted on linear co-ordinate paper, and hence the effective bandwidth, may be determined by any convenient graphical or mechanical method. To obviate the necessity for converting the results of the mechanical integration into the dimensions indicated by equation 4, it is convenient to transform this expression for effective bandwidth into a simple ratio of areas multiplied by some arbitrary unit of bandwidth. Multiplying both the numerator and denominator of equation 4 by 1 kc, equation 5 becomes

$$B = \frac{\text{Total area under squared response curve}}{\text{Area of 1-kc rectangle}}\text{kc} \tag{5}$$

Thus the effective bandwidth may be restated as being numerically equal in kilocycles to the ratio of total area under the squared response curve to the area of a rectangle 1-kc wide whose ordinate is $A^2(f_o)$. Further simplification may be introduced by plotting the ordinates as squared response ratios $A^2(f)/A^2(f_o)$ rather than actual squared response, and the abscissa as the deviations from resonance $(f-f_o)$ in kilocycles rather than the actual frequency.

Conclusion

The concept of effective bandwidth, insofar as noise measurements are concerned, is most significant when dealing with networks characterized by gradually changing frequency response functions. For a single elementary inductive-capacitive resonant network, the effective bandwidth in cycles per second may be determined analytically and is found to be equal to $R(f_o)/4L$, where $R(f_o)$ is the total series resistance at resonance, and L the total inductance. The circuit bandwidth, however, is equal to $R(f_o)/2\pi L$, provided the network exhibits a value of Q of about ten or greater. It is evident, therefore, that for such elementary networks the ratio of the effective bandwidth to the circuit bandwidth is equal to $\pi/2$, or 1.57 as shown in Figure 3. This ratio approaches 1.07 as the number of such isolated elementary stages arranged in cascade increases,[1] and approaches unity as the over-all response curve approaches the rectangular form shown in Figure 2.

The noise power developed across the output terminals of a network is a linear function of the effective bandwidth only when dealing with noise phenomena uniformly distributed throughout the frequency spectrum such as random noise which is due usually to the spontaneous motion of free charge in electric conductors. Noise phenomena of other distributions expressed in terms of average, effective, or quasi-peak voltage may be treated approximately by revising the exponent associated with the expression for effective bandwidth.[2] The magnitude of the new exponent will depend on the nature of the noise that is, its frequency distribution, and the mode of measurement.

Oscillographing Commutation

M. J. BALDWIN
MEMBER AIEE

TEXTBOOKS long have contained theoretical explanations of commutation, but the necessary tools have been lacking with which to obtain actual pictures indicating instantaneous values of current and voltage in coils undergoing this transition. The cathode-ray oscilloscope is the fundamental tool which now makes this possible. One method of obtaining such pictures is described in this paper, and is illustrated with typical oscillograms. The latter bear out, in general, the classical text-book material rather closely; in addition, the test curves are convincingly realistic, in that they are far from being smooth. This investigation was undertaken in an effort to obtain a better understanding of commutation, with the hope that this added knowledge might serve to point the way to improvements which would extend the range of application of d-c rotating apparatus.

Special Armature Used

The machine used for these experiments was a traction motor with series fields and a multiple-wound, three-coil-per-slot armature. The polycoil comprising these three coils was of the so-called "twisted-lead, orphan coil" type illustrated in Figure 1. Only one polycoil was used, on the assumption that all other polycoils, being normally of identical design, would have essentially equal characteristics. As indicated in Figure 2, the one polycoil used for the test essentially was normal in every respect, except that each individual coil had two small insulated wires, one electrically connected to the inside of the coil near each commutator riser (see points marked * in Figure 2), thence passing through the center of the conductor comprising the coil. These wires were brought out through a single small hole in the side of the loop, at the end of the coil opposite the commutator. The outside ends of each of these two small wires were connected to two slip rings. In order to investigate the three coils in the polycoil, therefore, a total of six slip rings was required, as is indicated in Figure 2. Figure 2 also indicates the designations used here for the six conductors, *A*, *B*, *C*, *a*, *b*, *c*, comprising the polycoil. In identifying a complete coil consisting of conductors *A* and *a*, the designation of the coil is the same as that of the top conductor, namely, *A* in this instance.

Figure 3 shows the connections schematically. It is easier to follow than Figure 2. For measuring current in any coil, the resistance drop in voltage caused by the flow of current is used. The coil becomes, in effect, a small d-c ammeter shunt.

Voltages which may be induced in the conductors are represented in Figure 3 by small arrows. If these voltages are added algebraically from slip ring 5 to slip ring 6, and if we assume the voltage induced in the coaxial wire in a conductor is equal to that induced in the conductor itself, then the only voltage which should appear across these two slip rings is that caused by the resistance voltage drop in the coil. Transient variations in this potential, therefore, may be considered as proportional to transient variations in the current flowing in the conductor. Similarly, variations in potential across slip rings 3 and 4 are proportional to variations in current in coil *B;* variations across slip rings 1 and 2 are proportional to corresponding variations in current in coil *C*.

It also is possible to read bar-to-bar voltage variations if we make one added assumption: namely, that the voltages induced in all conductors in a given slot are equal. In the commutating zone, where the flux density in the teeth is low, it would seem reasonable to make this assumption with negligible error. Referring to Figure 3, it will be found that coil *A* voltage can be read between rings 4 and 6; coil *B*, between rings 2 and 4; and coil *C*, between rings 1 and 3.

Typical Oscillograms

Figure 4 shows a series of 12 oscillograms, all for fixed values of load, speed, and rotation. The ones in the upper half show current in the three coils. The lower half shows voltages between the adjacent commutator bars to which the three coils are connected. In the top horizontal row and in the bottom horizontal row, each of the three current and voltage traces has been separated vertically to facilitate identification. The true vertical relationship is given in the two center horizontal rows of oscillograms.

The compensation adjustment producing the best observable commutation, by the black band method,[1] for this load and speed condition, is shown in the center column of oscillograms. For the oscillograms in the column at the left, the com-

Indicating Connection of Coaxial Leads to Slip Rings at End Opposite Commutator. Core Portion Cut Away

mutating-pole strength was excessive, or, in other words, the motor was "overcompensated." For those in the column at the right, the opposite is true; the machine had insufficient commutating-pole flux, or, in other words, was "undercompensated." For both the undercompensated and the overcompensated conditions, the sparking was, on the average, grade *d*. For the intensity of this sparking, refer to Figure 6. For the best commutation, shown in the middle column, the sparking was *b*.

The time sequence is, in all cases, from left to right. Also, for this clockwise rotation, the three coils commutate in alphabetical sequence; *A* first, *B* second, and *C* last.

Elapsed time is indicated by the fourth trace. This indication is obtained by measuring voltage in units of segment pitch between adjacent bars, by means of a pair of small brushes mounted on the side of one of the motor brush holders.

Figure 5 contains a second set of oscillograms of the same machine operating at increased current and lower speed. Overcompensated and undercompensated sparking are about equal. Commutation is between *c* and *d*, as graded in accordance with Figure 6. For best compensation, the commutation is black.

In order to see better the proportions, and in order to have time reference points, the curves from Figure 2 have been replotted on rectangular co-ordinates. Figure 7 shows the commutation on coil *A*, the first coil commutated; Figure 8 shows coil *B*, and Figure 9 shows coil *C*. This particular set of oscillograms has been chosen because the changes in slope are so sharp.

Commutation Sequence

In order to understand the oscillograms, it is first necessary to determine the instant at which a given coil is either short- or open-circuited, and also the corresponding instant for any other coil, which may affect the rate of change of current or voltage in the coil under observation. Figures 7, 8, and 9 each have a time reference scale, the unit for which corresponds to the time for the armature to travel a distance equal to the width of one-half of one commutator bar. Figure 10 indicates which conductors are short-circuited for each time reference point at which the short circuits are made or broken for the three sets of curves shown in Figures 7, 8, and 9.

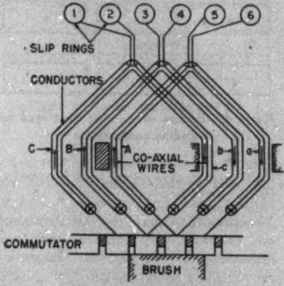

Figure 3 Schematic diagram of test polycoil connections

Bottom Conductors of all Coils are in Slot 1
Top Conductor of Coil *A* is in Slot 15
Top Conductor of Coils *B* and *C* are in Slot 16

Current Curves

Using the time sequence given in Figure 10, it is not difficult to discover the reason for most of the changes in slope of the current curves. Coil *A* is the first one commutated in this clockwise rotation, followed by the other two in alphabetical sequence. Coil *A* is short-circuited at time reference 0, and the short circuit is broken at time reference 5; coil *B* is short-circuited at 2 and the short circuit is removed at 7; coil *C* is short-circuited between 4 and 9.

Time reference point 9 marks the time of completion of commutation of the test polycoil. Point 6 would correspond to point 0 for the succeeding polycoil.

If the commutating pole is of correct strength, that is, the machine is correctly compensated, the current in the coil will reverse at a rate such that the current in the short circuit, at the time the short circuit is removed, is the same as the load current in the motor armature circuit. Coil *B* appears to meet this condition when correctly compensated, as shown at point 7 in Figure 8.

Neither coil *A* nor coil *C*, on the other hand, meets this requirement, either when "correct" or, especially, when "overcompensated." In both cases, the short-circuit current exceeds the load current for the point at which the short circuit is

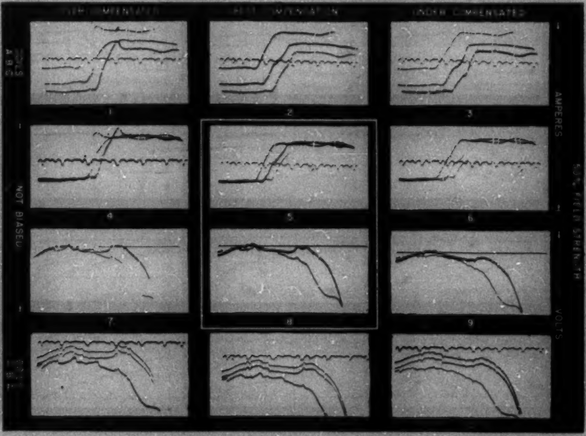

Figure 4. Oscillograms for 1,950 rpm, 450 amperes, clockwise rotation

broken. In spite of visual observation, the oscillograms appear to indicate overcompensation for the so-called "correct" condition. Point 9, "undercompensated," illustrates clearly the result of the commutating pole being too weak. The current in the short circuit here has not reached a value high enough at the time the short circuit is removed, and a spark is indicated in both current and voltage curves.

The rate at which current reversal in a coil takes place depends, in part, on the amount of commutating-pole excitation, but it also is altered by the presence of other short-circuited turns in the slot, which tend to reduce the speed of reversal. This is indicated by the change in slope of the correct curve at reference point 2 in Figure 7, when the rate of change of coil *A* is reduced by the short-circuiting of coil *B*. The reduction in the rate of change is even more pronounced for coil *B* at reference point 4 in Figure 8 when coil *C* becomes short-circuited by the brush.

The rate of change of current in a given coil, conversely, theoretically would be increased when the short circuit of the brush is broken in some other coil in that slot. At reference point 3 for coil *A*, the opening of a short circuit on coil *C* of the preceding polycoil increases the speed of reversal when undercompensated. Again, this is true of coil *C* for reference point 7 for the undercompensated condition. It is at this point that the short circuit on coil *B* is removed.

Voltage Curves

The voltage curves were taken principally in order to more accurately detect sparking, and as an auxiliary means of indicating time. The amplifier of the oscilloscope used did not have adequate capacitance-resistance product for the low frequency of the motor under test. Calculations would indicate about 32 per cent decay from the beginning of the voltage peak to the time when commutation begins. This accounts for the curves, shown in Figures 5 and 6, being below the zero axis instead of above. An approximate correction of 5 volts therefore, has been applied to the curves in replotting them for Figures 7, 8, and 9. The absolute values of the voltages shown are, therefore, very approximate. It is interesting to note how the changes in commutating conditions affect the shape of the voltage curves. Sparking is indicated rather clearly. Take time reference point 9, Figure 9, for example. Here we see overcompensation indicated by a peak upward; undercompensation, by a peak downward. It is doubtful if the voltage curves taken alone mean a great deal to an observer, but, in conjunction with the current curves, the two appear to tell whether there is sparking, and whether the sparking is caused by too slow or too rapid reversal of coil current.

Summary

To the designer of electric equipment, even these few curves indicate clearly the entire problem of commutation. The effect of variation in the adjustment of the commutating pole and of mutual inductance upon the rate of change of current is shown. The difficulty of getting the several coils in a slot to commutate equally is revealed. The need for brushes to absorb the residual voltages under the best of conditions is suggested. Commutation theory is proved to be correct, and a better understanding of commutation is promoted.

Beyond this point, what use can be made of the oscillograph in extending the range of commutation? At this time we cannot answer this question. It is like asking whether the microscope is of any use as an instrument after having employed it on but one specimen. If we consider as specimens each type of armature coil, pitching, and arrangement, and if we consider the oscilloscope as a microscope for the examination of each, this device could be the tool to assist the designer to select the ones that are better and, what is more to tell why they are better. In this manner, it ultimately may point the way to extension of the commutation range of d-c apparatus.

Appendix. Testing Technique

The oscillograms shown in this paper are typical. These, and others like them, were the result of a series of experiments performed with varying degrees of success. The remainder of this paper is devoted to a summary of what was learned regarding the technique of taking this type of oscillogram.

Magnetic Oscillographs

The magnetic oscillograph has two features which would seem to permit its use in connection with tests of this type. First, it usually can be used directly connected to the exploring coils without an amplifier. Second, it has several elements, permitting simultaneous photography of current or voltage in several coils.

On the other hand, the speed of response of all elements of the magnetic oscillograph must be exactly equal, and also must be adequate for the speed of machine to be tested. Although some oscillograms were attempted in connection with this particular test machine, the slow speed of response of available elements resulted in oscillograms of questionable value. At 1,950 rpm, the changes in the slope of the curves occur one-half of a commutator bar apart, corresponding to 82.5 microseconds. In order to give a good record, the oscillograph in this instance should be able to follow a square wave with a frequency of 6,050 cycles per second. The magnetic oscillograph was abandoned in this case because of the lack of matched elements good for this frequency.

Cathode-Ray Oscilloscope

The cathode-ray oscilloscope is suited better to this application than the magnetic oscillograph. This is principally because the electron beam has no inertia, and, for the frequency dealt with here, will follow the changes in rate accurately. The operator also is able to watch these changes take place. Some magnetic oscillographs, by means of revolving mirrors, possibly may permit some observation, but the cathode ray oscilloscope is excellent for large-scale images which readily may be photographed where oscillograms are desired.

The cathode-ray oscilloscope also must be of suitable size and design. If a 3-inch size otherwise is equipped suitably, it may prove adequate for preliminary observation, but, for photographs, a 5-inch size is much better. All oscillograms shown here were made with a 5-inch oscilloscope. The time constant of the resistance-capacitance network of the Y-axis amplifier should be as large as possible. These photographs were taken during the latter part of the war period, when any oscilloscope was difficult to obtain. The best one available had a time constant of about 0.050 second with which to measure commutation rate in zones occurring 0.025 second (at 600 rpm) apart. The decay in ampere signal can be accounted for easily as the current before and after the transient is of known value, but to estimate the voltage values in the commutating zone is not accurate, as has been noted already. Oscilloscopes now are available with Y-axis amplifiers good for much lower frequency than the one used here. The oscilloscope should be selected to suit the speed of the machine tested if voltage values are to be estimated accurately.

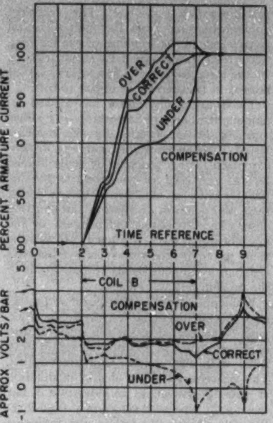

Figure 8. Commutation of coil *B*

The oscilloscope used should be provided with the single-sweep feature, which permits displacing the spot off the screen to the right, and initiating the sweep externally. The possible adjustment of sweep frequency should be adequate for the range of test-machine speed to be covered. While this is not important when the single sweep is being used, for visual observation it is desirable sometimes to use the recurrent sweep.

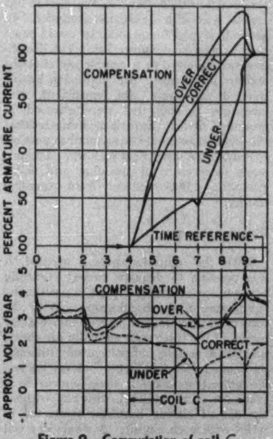

Figure 9. Commutation of coil C

Sweep Initiation

As has been noted, the oscilloscope was of the type permitting external initiation of the sweep. All the oscillograms shown were taken this way, using a small impulse generator for initiating at identically the same position on each revolution of the motor. A permanent magnet was mounted on the coupling of the machine being tested. As the machine revolved, this magnet passed across the face of a stationary electromagnet about the size of an ordinary spool of thread and induced an impulse in its winding. This impulse proved entirely adequate for initiating the sweep, with no amplification.

There were four of these electromagnets mounted on a yoke, each just ahead of a commutating zone. The yoke was arranged to be shifted, to obtain the desired points of initiation of the sweep. Between the external sweep terminals of the oscilloscope and the four coils, a selector switch was interposed in the circuit to permit the operator to examine quickly commutation at any of the four brush positions.

Experiments also were made using a photoelectric, light-sensitive cell to initiate the sweep. This cell would detect the reflection of light from a white dot on a revolving black drum, with sufficient output when amplified to initiate the sweep. Although not used for making these oscillograms, a photoelectric cell might prove to be a convenient means of initiating the sweep of the oscilloscope.

Time Indication

Time may be indicated on the oscilloscope in several ways. To be most useful, it needs to be indicated, not in terms of seconds, but in terms of commutator bars. The indication used here was obtained from two small brushes mounted on the edge of a brush holder, and separated just far enough apart to obtain an intermittent indication of bar-to-bar voltage when the two brushes spanned a mica. The brushes, when working properly, give a good time indication, as indicated in Figure 11. The upper curve indicates the signal obtained when connected to the vertical or Y oscillograph circuit. The lower is the same signal applied to the Z, or electron accelerator grid circuit, with the same sweep but no Y signal. Improved probes with coil-spring-backed, drafting pencil leads as brushes, have been developed subsequently, which should assist in obtaining better time indication curves in the future.

Slip Rings

The proper design of slip rings, brushes, and brush holders is important. Initial tests made, using a single brush per ring, were not satisfactory. Subsequent tests

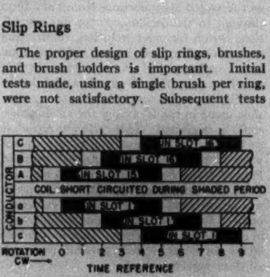

Figure 10. Commutation sequence

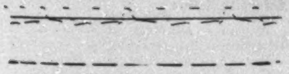

Figure 11. Typical time indications

with two brushes per ring turned out much better. Apparently, both brushes are not apt to lose contact with the ring surface at the same time, so two operate successfully where one does not. A reasonably well-ground surface on the rings, however, is essential. The slip rings necessarily do not require much space. In this test, six brush holders and rings were held within $2^{7}/_{16}$ axial inches. Figure 12 shows the final brush holder and the rings which are located below the armature back-end windings. The brushes used were of silver-graphite composition.

Multiple-Exposure Method

To compare the three coils from a commutation standpoint, photographs to the same scale and time reference were needed for all. Two methods were employed: the first simply being to adjust the oscilloscope and obtain one exposure for each coil and one for the time reference. The only difficulty found with this system was that there was enough creep in the length of the X axis, one way or the other, to throw off the timing before all the exposures were completed. It was not possible to switch from coil to coil without getting a powerful condenser discharge, sufficient to paralyze the oscilloscope temporarily. No common, full ground between two coils is possible, since such a connection would short-circuit the coil. The sweep being initiated once each revolution, the frequency of recurrence was sufficient to permit watching the effect of changing compensation without visual discomfort.

Single-Exposure Method

A second method of taking the oscillograms, therefore, was devised which permitted taking four exposures with one opening of the camera shutter. This was made possible by connecting the oscilloscope, in rapid succession, to each of these coils and to the timing-signal brushes. A revolving distributor was used, consisting of segmental copper rings with suitable brushes. This was arranged to connect one circuit at a time through to the oscilloscope for one revolution, switch for one revolution, connect for one revolution, and so on until all four curves had appeared on the screen. In this way it was possible to get the exposures in sufficiently rapid succession that any possible creep in the X axis of the oscilloscope could be neglected. This cycle was repeated as long as desired and was photographed when convenient. The pictures shown in Figures 4 and 5 were taken in this manner. From the visual standpoint, this method was not as good as the multiple exposure, because the same signal appeared but once in every eight revolutions. Despite the bad flicker, however, it was possible to watch all three coils commutate.

The paralyzing of the oscilloscope has been mentioned in connection with the multiple-exposure method. This discharge apparently came from the high dielectric capacitance of the windings of the machine under test. It was avoided in the distributor by the interposition of a temporary, partial ground in transferring from coil to coil.

The rotating distributor has several requirements that are important. It either must be driven directly by the machine tested, through a suitable gear box, or synchronized to that machine by some means. Selsyns were used for synchronizing the distributor with the machine on test in taking these photographs. Selsyns permit shutting down the distributor, independent of the machine under test. Arrangements must be made to remove the static charge from each distributor segment before connecting it to the oscilloscope.

When operating the distributor and working with the current curves, all circuits either must be connected to the slip rings in turn, or else grounded to prevent picking up stray fields with the unused, ungrounded line. This prevented the use of grid modulation of a straight sweep as an indication of bar spacing, at least with the circuits used here. For this reason, the timing was indicated by deflecting the spot along the Y axis, similar to upper timing wave shown in Figure 11, rather than by modulating the grid.

Shielding and Grounding

Nothing is more important in making preparations for a test of this type than to provide adequate shielding of circuits. The voltage drop in the armature conductor, when handling 830 amperes, is but 230 millivolts.

Every precaution is required to shield the circuits from the slip rings to the oscilloscope; otherwise the weak signal to be observed will be obliterated by stray field pick-up from other machines in the vicinity. Shielding is not as important when obtaining voltage curves. Twisted leads did not prove adequate unless wrapped with grounded copper wire. Final tests were conducted with nothing in the circuit but coaxial wire with all sheaths grounded. In general, it was found best to avoid more than one ground connection. The distributor was revolved in a completely enclosed and grounded case. All connection boards were of minimum size, consistent with creepages needed, and were encased in grounded covers. Experience indicates that the distributor should be as small as possible to reduce the stray field pick-up. The primary importance of shielding and single grounding was learned only from expensive testing.

Biasing Curves

With the multiple-exposure method, it was possible to displace curves vertically between exposures by using the positioning equipment of the oscilloscope. With the rotary distributor, the current and voltage curves of the three coils normally are superimposed, making identification difficult, particularly for the jagged voltage curves. To permit separation, these curves were taken for each condition, with and without the use of biasing batteries connected in series with each circuit. A single dry cell per circuit, shunted by an adjustable voltage divider, permitted reduction of the battery voltage to obtain the desired curve displacement.

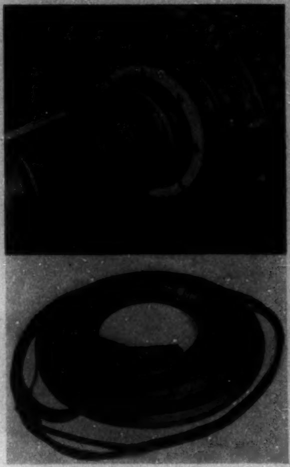

Figure 12. Brush holder and slip rings used in tests

For the voltage curves, a second set of batteries was needed which, in this case, was of the radio B-type. Only one set of batteries was connected at a time in order to keep stray pick-up at a minimum, particularly when working with the current curves. The rotary distributor served as a device for applying the d-c bias just ahead of the initiation of the sweep, thereby momentarily displacing the curve as desired.

Future Tests: Modified Multiple-Exposure Method

In the event that tests of a similar nature are to be made in the future, a modified form of the multiple-exposure method should be considered. A distributor of the type used for the single-exposure method would be provided, but would be operated only by hand, as a quick means of selecting the coil to be scanned. If, by the use of this device, the multiple exposure of the several coils can be accomplished within 30 seconds, no appreciable error in time relationship between the curves should result, as the creep of the X-axis sweep is perceptible only over several minutes.

The electronic switch also might be brought into use to permit observation of the current and voltage waves of a given coil simultaneously. To do so may require an oscilloscope larger than five inches. With the better visual condition resulting from the more frequent sweep, coupled with the ability to observe both rate of current change and voltage peaks at the same time, there would be little about the commutation that could not be seen at a glance. The necessity of changing grounds between coil observations will require the selector switch to be moved from coil to coil. This method then provides a means for visual observation of commutation, as well as for obtaining oscillograms.

Poor brush riding and improper brush fit may be detected. By switching the initiator selector from brush to brush, all brush positions may be examined. Such an arrangement might permit better commutation adjustment than can be obtained currently by the black band method.

Discussion

D. B. Hoover (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The method described in the paper appears to be a good means of evaluating the merits of various types of d-c armature windings with respect to commutation. It stresses the importance of mutual inductance of the coil sides during commutation, and serves as a practical means of checking the effects of mutual inductance in any given winding.

The mutual inductance between coil sides of a given winding may be increased by increasing the number of bars spanned by the brushes, if it is assumed that the brushes maintain intimate contact with the commutator bars spanned. In this respect it would be interesting to study a plain, multiple-wound armature, say with two bars per slot and half slot chorded, using brush widths spanning two, three, and four bars. A study of this armature might prove the intimacy of contact that exists between the bars and the brushes.

It appears that the commutator roughness might affect the results of tests performed on some types of windings. Was this found to be the case on the machine tested?

M. J. Baldwin: As suggested by Hoover's discussion, a broad field of investigation is opened by the use of the oscillograph for studying commutation. So far, the only work done here has been with the winding described in the paper.

Oscillographs have been made with different brush widths. Perhaps the results of these tests may be published at some future date.

Although we do not have illustrations, the effect of poorly riding brushes has been observed. The current traces become erratic and nonrepetitive, whereas the opposite is true if the brushes are riding smoothly.

Effects of Commutator Surface Film Conditions on Commutation

COMMUTATION, to the d-c designer, is considered fundamentally from the standpoint of the reactance voltage produced in the coils being short circuited by the brushes. This voltage can be considered as being produced by a changing and reversing current through the self and mutual inductance of the armature coils being commutated, or it may be thought of as being produced by the armature coils being commutated, cutting a resultant armature field, stationary in space, located in the interpolar space between each main pole and produced by load current in the armature coils themselves.[1] In any case, the designer is interested in proportioning his machine so that the magnetic structure and the winding combinations and commutator and brush rigging, give a structure which develops the desired voltage, carries the designed current and will commutate successfully. Successful commutation is defined in C-50 2.085[2] as follows: "Successful commutation is attained if neither the brushes nor the commutator is burned or injured in an acceptance test; or in normal service, to the extent that abnormal maintenance is required. The presence of some visible sparking is not necessarily evidence of unsuccessful commutation." In addition to the correct proportioning of the design of the d-c machine, which will reduce to a minimum the resulting reactance voltage of the coils being commutated, various other factors enter into the commutating problem. This paper primarily will discuss those effects on commutation produced by surface films of various types on the commutators, but in addition, it will necessarily also cover those other factors which are involved in the commutating problem.

Electrical and Mechanical Factors Affecting Commutation

Contact drop between the brushes and commutator surface and the resistance of the brush itself, as well as the resistance of the armature coils being commutated, limit the short circuit current which can flow in the brush and the coil being commutated. The lower the reactance voltage of commutation, the lower the short circuit current. Also, the higher the contact drop and the higher the resistance of the brush itself, the lower will be the short circuit current. However, since the load current, as well as the short circuit current, has to pass from the commutator to the brush and through the brush body, there is a limit to the permissible voltage drop at the contact and to the resistance of the brush body itself. Too high values for these will result in too great a loss at the brush contact surface. At some value of short circuit current, which is not a constant value, but which depends upon many factors, sparking at the brushes will occur. If the sparking is minute, it probably will not cause burning of the commutator bars or the brushes, and if it does not become cumulatively worse, no harm will result.

Assuming a correct design and correct electrical adjustment, commutation is adversely affected by lack of intimacy of contact between the brush and the commutator bars. It can be shown[3] that commutator bar to bar roughness as little as 0.0001 inch (this does not refer to eccentricity of the commutator as a whole) can cause sparking, while the same machine, with less than this bar to bar roughness, will have black commutation.

Commutator Films of Earlier Periods

Copper is used universally for the bars in commutators because; it is relatively cheap, mechanically it is fairly strong, it does not draw beads on arcing and because in uncontaminated atmospheres, it forms a film on its surface that assists commutation. Until recent years, the important part played by this film surface was not fully appreciated in the art. In the old days, the best operating d-c machines had chocolate colored commutators. This was before the days of high commutator surface speeds, when machines had low ratings, operated at slow speeds and had relatively easy load cycles. In those days, there were few brush grades, no treated brushes and much less was known about brushes and commutator surface films.

With the introduction of electrographitic brushes 30 or 40 years ago, and the building of larger, higher speed, d-c machines, with more difficult loading cycles and more contaminations of atmospheres in industrial plants, commutator surfaces of unfamiliar types and colors began to develop. With the introduction 20 to 25 years ago, of newer grades of electrographitic brushes produced under different manufacturing conditions, commutators with black surfaces began to develop in certain steel mill applications. Peculiar colored commutator surfaces occurred in chemical industrial plants and paper mills. Most of these machines with black commutators, operated successfully, but the customers objected to the color of the commutators. Cleaner or scouring brushes were brought out about this time. These brushes had the properties of mechanically abrading the commutator surfaces so as to reduce the amount of discolored film on the com-

Paper 49-29, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 22, 1948; made available for printing December 21, 1948.

C. Lynn is manager of the d-c engineering department, and H. M. Elsey is consulting chemist, research laboratories, Westinghouse Electric Corporation, East Pittsburgh, Pa.

mutator. These brushes were used, few in number, and were generally spiraled around the commutator, so as to continually lightly scrub the commutator film surface. The amount of scouring action was controlled by the number of brushes used on a given track. Even in case of bars, slightly burned from poor commutation, these brushes were used in maintaining a cleaner commutator surface. Usually, most machines, whose commutator surfaces have been reconditioned by grinding or handstoning, will commutate successfully, at least for a period of time.

When a new or freshly ground commutator is placed on load, and after a very few hours of operation starts to take on a reddish hue color, this is, in general, an indication that the film surface being formed on the commutator is of the right type to produce successful commutation.

Even before World War II started, the real importance of commutator films began to be appreciated. It was known that lightly loaded electro-graphitic brushes could develop a chatter on the commutator surface. This chatter was related to the type of film formed on the commutator surface by continued operation of these lightly loaded brushes. The brushes, themselves, developed an extremely high polish on their contact surfaces, and there was an appreciable movement of the brushes in the brush holder boxes. This could be determined by observing the polish on the sides of the brushes where they rode up against the brush box. The actual movement of the brush in the box was much greater than the actual out-of-roundness of the commutator, as could be proved easily by slightly sanding the commutator surface to remove the highly polished film. Usually machines which developed this chatter, would operate in a normal manner if the film was removed and if the load on the machine was such as to give a normal loading of the brushes, that is, current densities 40 to 60 amperes per square inch.

A phenomenon known as copper picking is sometimes experienced in the operation of commutating type d-c machines. When this occurs the surface of the brushes have small flakes of copper embedded in their surfaces. The size of these flakes may be extremely small, so that a magnifying glass is required to see them, although sometimes pieces of copper, up to a 1/16 inch square or even larger, may be found. This condition is always accompanied by threading or grooving of the commutator, because this results in certain portions of the commutator surface being rubbed by copper instead of by carbon. This condition usually occurs due to a build-up of surface on the commutator, and the finally breaking through of this surface at points on the brushes, with a resultant deposit of copper flakes on the brush at these points. When this happens, a lower resistance path to the flow of the current between the commutator and brushes occurs at these points, and the current distribution in the brushes is no longer even. Since it is impossible for all the current to be carried at these few points, other points will also be similarly affected and sometimes many of these threaded tracks occur on the commutator surface. This can lead to poor commutation. The only cure in this case is to remove the copper from the face of the brushes, either by picking it out with a knife or resanding the brush faces to accomplish the same purpose. The commutator surface should be reground so as to permit an even freshly ground copper surface, with the hope that a normal surface film will be formed evenly across the surface, and the picking up of copper eliminated. Certain other conditions, as will be mentioned later, also cause picking up of copper.

In the early 20's, it was discovered that in extremely cold weather, particularly in the northwest part of the country, brushes wore rapidly when the humidity was quite low. This applied to carbon, graphite, and copper graphite brushes. Sometimes a set of brushes would wear out overnight. Some substations in the north overcame this by humidifying the substation when the humidity became very low.[4] Machines have been built where humidification of the ventilating air to secure improved current collection, was an original part of the equipment. Experience in the past has indicated that more than normal brush wear will occur if the humidity content of the ventilating air of the conventional machine is less than $1^1/_2$ grains of water per cubic foot of air. This depends somewhat upon the current loading of the brushes. With the advent of d-c application to military aircraft, where generators had to operate at extremely high altitudes where the moisture and oxygen content in a given volume of air was low, extremely rapid brush wear was encountered.

Consideration of Commutator Surface Films

The first worker to seriously speculate as to the precise nature of the film which forms on the copper commutator in air was Baker.[5] He assumed that the film was composed essentially of copper oxide and that it ranged in thickness from 3×10^{-6} to 3×10^{-5} centimeters. Ten years later Van Brunt and Savage[6] stripped a film from a commutator bar and reported a total thickness of 5.4×10^{-6} centimeters of which only 2.1×10^{-6} centimeters was copper oxide. The balance of this film was found to consist essentially of an upper graphite layer which had a thickness of 3.3×10^{-6} centimeters. In interpreting this analysis and other data, these workers cited, assumed that there were at least three components in all normal films on commutators or copper slip rings which are operated in air, and of these constituents, they viewed the graphite as the most essential. This is the component which functioned as a lubricant. It is held to the tarnish film of copper oxide by bonds, which are greater than the bonds between adjacent layers within the graphite surface, and it performs its function as a lubricant through the presence of an absorbed layer of water vapor. For this reason brushes wear very rapidly in atmospheres of low absolute humidity and justifies the humidification of the ventilating air around current collecting parts of rotating machinery to a minimum of at least two grains of water per cubic foot of air. The lack of water vapor in the upper air was responsible for rapid wear of brushes on electric apparatus of high flying airplanes. Martinez[7] has observed a water content as low as 0.00075 grains per cubic foot at an elevation of 40,000 feet. If $1^1/_4$ grains of water vapor per cubic foot of air is absolutely necessary as a minimum for good brush life and performance at the earth's surface, it is no wonder that special treatments had to be discovered and applied to aircraft brushes which were forced to operate in exceedingly dry atmospheres encountered at high altitudes.

While admitting that graphite and copper oxide are both normally observed in commutator films, we suggest that a simpler mechanism of film maintenance and formation is more probable. In 1927 Vernon[8] reported that copper which was exposed to air, free of hydrogen sulphide, acquired an almost transparent tarnish film at room temperature, which was wholly composed of copper oxide and that this film was protective to the underlying copper in atmospheres which readily corroded unfilmed copper. However, if an unfilmed sample of copper was exposed to air containing as little as one part in 35 million parts of hydrogen sulphide, the tarnish film which formed was not protective to the underlying metal and contained sulphur out of all proportion to the concentration of hydrogen sulphide in the air. For example, while the oxygen content of the air is 210,000 parts per million and the hydrogen sulphide content was only 0.03 parts per million, the tarnish film formed in such an atmosphere consisted of 10 to 15 per cent of copper sulphide and 90 to 85 per cent of copper oxide. If an almost undetectable trace of gaseous impurity in the air can completely alter the character of the tarnish film on the copper by altering the character of the chemical reaction, there would seem to be no need to look for a complicated explanation for the effect of 3,600 parts of such a chemically active gas as water vapor on controlling the chemical nature of a tarnish film.

Hydrogen sulphide as an air impurity has been purposely chosen for discussion first, because this gas is present in many industrial atmospheres, and is the controlling cause of poor commutation and brush life in most steel mills, and even in some central station power plants. It is present in such high concentrations in certain areas in kraft paper mills and certain chemical industries, that it is almost impossible to operate commutating machines in those locations.

During the war, it was found that certain compounds, the metallic halides,[9] could be incorporated in brushes and that these treated brushes would give satisfactory life and performance on aircraft generators, when these were operated in air almost completely devoid of water vapor. Since this class of brush was apparently able to control the type of film on a commutator in the absence of water vapor, a gaseous constituent normally required for good commutation, it was thought that similar brushes might maintain satisfactory film conditions on industrial machines which were operating in atmospheres on the earth's surface containing such undesirable impurities as hydrogen sulphide. Many applications of brushes containing metallic halides, have been made and a substantial percentage of the large electric machines in steel mills now are fitted with so-called altitude treated brushes. Hydrogen sulphide has been the cause of poor commutation in so many industrial locations, that when a new complaint is received, it is well to look for evidences of this gas in the atmosphere. Its presence or absence is determined readily by the character of the film on the commutator outside of the brush tracks. The concentration which can cause trouble can be below that which is susceptible to the sense of smell. If there is no evidence of copper sulphide (and this is recognized readily by its characteristic color) on the edges of the commutator, or on the copper bus bar in the neighborhood of the machines, hydrogen sulphide is probably not present in damaging concentrations. Several instances of poor commutation and short brush life have been observed on machines in localities where hydrogen sulphide might be expected to be present on account of the nature of surrounding industrial plants.

In one instance, an exciter in a large power station at times sparked badly over extended periods, but close examination of the commutator and the surroundings indicated the complete absence of hydrogen sulphide. However, this station was not far distant from a battery of coke ovens, and it was found that whenever prevailing winds carried the gases from these ovens towards the station, poor commutation was observed and sparking decreased and at times even became black after periods of time, with the wind in the opposite direction. In this connection a most interesting discovery was made during one of the bad commutation periods. Through an accident, chlorine gas was released into the atmosphere of the station, from which the ventilating air of the exciter was secured, and the concentration was so high that it was necessary to open all the doors and windows to remove the irritating gas as quickly as possible. Immediately following this incident, it was noticed that the sparking had ceased and the commutation was black. There had been no change in load or any other operating conditions. The station operators had no clues as to the cause of the change in commutation, and it was only when an inspection of the commutator showed an indication of a change in color of the copper not covered by the brush tracks, that the incident of the release of chlorine gas was brought out. In our studies of this surface film commutation problem, we had found that traces of free halogen gases would form and maintain a copper oxide film on copper under high altitude conditions. Hence we at once assumed that it was the chlorine itself which was responsible for the improved commutation. Some weeks later, during another period of bad commutation, in the presence of a number of observers, we released a small quantity of chlorine gas into the entering cooling air for the exciter. Within a few seconds black commutation followed, and it was noted that no visible sparking was observed for a period of two weeks thereafter. From that time on, commutation was maintained at high quality by the occasional use of chlorine gas, until the installation of an air purifying equipment, which is described later, could be made.

Another power station located in the heart of the Allegheny Mountains, surrounded on all sides by hills, has located near it a burning culm heap. This station is in the heart of the Allegheny fog belt and is subject to bad down-draft conditions, which result in stack gases as well as fumes from the culm pile entering the station in relatively large volumes. Evidences of hydrogen sulphide were found on the bus bars in the station, and for that reason it might be assumed that this gas was responsible for the difficulties in commutation observed. It is, however, our feeling that in the case of this unit, the primary offender here is not hydrogen sulphide, but hydrocarbon vapors or other carbonaceous gases from the stack and the culm pile. An examination of the brushes on the machine showed nothing abnormal from a physical standpoint, but it was observed that the copper shunt wires were coated with black adherent deposits, which on analysis proved to be substantially carbon. Tinned copper surfaces were free of this tarnish. This observation suggests, therefore, that the possibility of a copper surface of a commutator, at times, may develop an objectionably high friction film which may be so thin as to be almost transparent, through the catalytic action of copper on carbonaceous vapors in the cooling air. It is well-known to chemists that copper greatly accelerates the formation of sludges in lubricating and transformer oils which are exposed to air. In a similar manner the hot copper on the surface of the commutator may convert the hydrocarbon vapors into resinous bodies which will adhere to the surface of the commutator as readily as they do to the copper wires of the shunts on the brushes. While pitch and other hydrocarbon fumes may not injure commutation through varnish formation, such a reactance mechanism would explain the damaging effects of the paraffin, oil, grease, and other carbon compounds when these are present at a brush copper interface through extended periods of time. It is well-known that a momentary application of paraffin may stop brushes chattering, but that a repeated use of this palliative will lead to undesirable commutation.

The use of chlorine in controlling the commutation in a central station when the air was contaminated with pitch fumes, was mentioned before. We have as yet suggested no mechanism for the improvement which was observed by the action of traces of this gas. It is one of those which is said to cause high friction and other undesirable commutating conditions when it is present in an industrial atmosphere. We have confirmed its effect on brush friction, but we cannot explain how an increase in brush friction will destroy a bad film condition and result in black commutation. It was our first thought that the poor commutation in question was caused by an inadequate copper oxide film on the commutator. We thought that the film was so thin that bare copper might be exposed, and it is known that the friction between bare copper and brushes is high and this could lead to chattering, with resultant sparking. We had assumed that the chlorine would attack the bare copper to form cuprous chloride and this in turn would be oxidized to copper oxide to form the desired normal film. Since, however, finding a resin or film on the copper shunt wires, we suspect that possibly chlorine functions by chemically attacking and destroying the undesirable varnish film formed from the pitch fumes. We are open to suggestions as to the true explanation of its beneficial effect, but we do think it most interesting that a trace of this corrosive, irritative, and otherwise highly objectionable gas, corrected bad commutation when all other attempted cures failed.

It is our belief that the phenomenon of copper picking, which is a very serious problem of commutation, is not caused by defective brushes of a given grade or by the application of an improper grade, but that this is associated with contaminated gaseous atmospheres. Experience has indicated, particularly heavy copper picking when machines operate in gaseous atmospheres containing hydrogen sulphide. Electrographitic brushes which are operated on a commutator which is filmed to a substantial percentage with copper sulphide, will almost always contain copper in the faces of the brushes. It is customary to assume that copper is transferred from the commutator to the brush face by some process similar to electrolysis, in which the copper dissolves at the anode, migrates through an electrolyte, and deposits on a cathode. Even if the existence of a mono-layer of tightly absorbed water vapor on a commutator film is assumed, we question if the mechanism by which the copper is transferred from the commutator to the brush bears any similarity to true electrolysis. We suspect that copper sulphide is not attached as firmly to the commutator copper as is the copper oxide, and that the sulphide film, in general, is thicker than the normal oxide film, and that fragments of copper sulphide break off and become embedded in the face of the brushes. Once embedded in the face of the carbon brush and removed from repeated exposure to the oxidizing action of the air, the sulphide particles are soon reduced by the carbon to metallic copper, and as such act as abrading or cutting tools on the commutator. Hence commutators are always found to be threaded or grooved, when copper is observed in the face of the brushes. An extreme grooving of commutators is customarily observed in areas contaminated heavily with hydrogen sulphide, particularly in kraft paper mills.

Current Collection in Hydrogen

The operation of brushes in a hydrogen atmosphere might be expected to avoid many of the troubles so frequently encountered in air operation. The reasons for operation of large a-c turbogenerators and synchronous condensers in hydrogen, have been covered in many papers in the past. D-c machines cannot make the same gains by similar operation and, therefore, there is not the demand for their operation in hydrogen. A turbogenerator requires the bringing out of the shaft through the case of the machine, for connection to the turbine shaft which drives it, and satisfactory operating hydrogen seals around the shaft have been developed. It is, therefore, quite simple to extend the shaft on the other end of the generator and operate the collector rings and the direct connected exciter for the unit in air. Operation of the collector rings and the exciter in hydrogen would result in many complications, particularly in regard to maintenance, especially since turbogenerator units are operated for periods of one in two years without a shut down. This necessitates changing both the collector ring brushes and the exciter brushes on the run, and suitable arrangements have been made for doing this.

In the case of synchronous condensers, some units have been built and are in successful operation, and other units are now building, using direct-connected exciters which together with collector rings, are operating in hydrogen. When this is done no shaft seals are required. Unfortunately, short brush life is not unknown on the collector rings of hydrogen cooled machines, with the collectors operating in hydrogen. Several years ago, after several brush grades had shown unsatisfactory wear on a hydrogen cooled synchronous condenser, a trial was made using halide-treated brushes. The original set of brushes is still in service on this machine. The quarterly inspection, to blow out carbon and metal dust and replace brushes, has been replaced by annual inspection, and the brushes promise an extremely long life as originally predicted by Baker[10] for brushes operating in hydrogen services. This original trial installation has been followed by others.

Commutation in hydrogen presents no particular problems. If the machine is designed so that it will operate satisfactorily in air with conventional brushes, it will also operate satisfactorily in hydrogen. If, however, sparking is present, the brush wear may be higher than in air and in that case the relative humidity should be kept below 10 per cent, otherwise extremely rapid brush wear will result. The voltage drop between the brushes and the commutator will be lowered somewhat when operated in hydrogen, as compared with operation in air, but this lowering is not so great as to adversely affect commutation.

Silicone Vapor Films

A very pronounced effect on commutation, of the action of a detrimental commutator surface condition, occurred during the war, when the first experimental submarine silicone insulated d-c motor was developed by Westinghouse. This double armature machine, which had about 40 per cent more rated output in the same weight and space, was totally enclosed and, of course, was worked very hard at the increased rating.

It was first tested as an open machine, taking air from the room at the middle, between the two armatures and discharging the heated air, back into the room, at the commutator ends. This unit was able to deliver 10 per cent additional output beyond its rating as a silicone insulated motor, under this condition of operation.

However, when it was enclosed and cooled by recirculated air, the commutation got bad after several days operation at this high loading. When this occurred, the voltage drop at the brush contact increased to two or more times normal values. By shunting current from the commutating field winding, it was possible to bring the brush potential curves, that is, the voltage drop at the brushes, back to a somewhat normal value and also materially reduce the sparking. The amount of current to be shunted was very great, corresponding to an excessively large commutating pole air gap. Continued operation in this manner, however, resulted in the commutation becoming bad again to the extent that the machine had to be shut down.

A film formed on the commutator surface, dark in appearance, which could be rubbed off easily. This was a carbon thrown down on the commutator and was responsible for the high voltage drop at the brushes and the resultant sparking.

Since the machine was operating at quite high temperatures, under this high loading, an attempt was made to cool the commutator by by-passing some of the air, directly from the outlet of the air-to-water heat exchanger. This resulted in some lowering of the commutator temperature but it did not improve the commutation. The commutator was cleaned and the test repeated with the same untoward results. However, when the same test was repeated, with the machine not enclosed and operated with a nonrecirculated ventilating system, it again successfully carried the 10 per cent overload continuously, without the formation of a detrimental film on the commutator or without the reappearance of the sparking. Once more, it was enclosed but this time it was operated at reduced load, with successful commutation. The load was increased until finally its rating (as a silicone insulated motor) was reached and it successfully passed the 17-day continuous load test at this load. The additional 10 per cent overload, as an enclosed machine, was just beyond its ability. This is the first instance on record of a large d-c motor encountering commutation trouble on account of the vapors of silicone varnish on its windings, forming a detrimental film on the commutator surface. In investigating this trouble, measurements were made to determine whether any vapors were given off by the silicone varnish, but none were found. Later investigations showed that the concentrations, which would give trouble in commutation, were far below that which could be determined by the apparatus used at that time, for detecting the vapor content.

At that time, it was not known that silicone vapor would cause rapid wear of the carbon brushes, even under a condition of successful commutation, as this large motor operated at relatively low speed and was not operated sufficiently long on test, for rapid brush wear to be encountered. This condition was first discovered at a Navy Laboratory, when a machine, that originally had class "B" insulation, was rewound with silicone-insulated coils. This was a relatively large high-speed d-c generator, totally enclosed, with a recirculatory ventilating system. The results were first indicated by the presence of low insulation resistance to ground of the windings. Upon opening up the machine, the presence of a large amount of carbon dust was found on the windings and a correspondingly short brush life. Further tests proved that rapid brush wear could be produced on a duplicate size generator, having class "B" insulation by simply placing into the ventilated air path, some coils covered with silicone varnish and heating the coils to any desired degree by passing current through the windings. Measurements have shown that a very minute amount of silicone vapor, 10 parts per million, show more than normal wear, while 200 parts per million produce ruinous wear, when recirculated air is used for cooling the machine. By opening the ventilating system to the atmosphere, the concentration will be reduced to a nondestructive value.

Duplicate results have been produced in the laboratory on small scale models, and attempts to thoroughly cure the silicone varnish by long time, high temperature bakes, have not produced a complete cure. Tests have indicated that it is possible to reduce the concentration, in a recirculatory system, to a sufficiently low value by suitable chemical filters. Operations, at lower than maximum permissible brush current densities, are a help in the right direction. The best method of eliminating the deleterious effects of silicone vapor on commutation, is to design and operate d-c machines, with silicone insulation, as open-type machines. A suggested design is to use separate ventilating systems for the current collecting parts of the machine and for the core and windings. This introduces some complications in design and operation.

Removal of Films by Scouring Action

Sometimes brushes, known as cleaner brushes, which are either inherently abrasive or have some cleaning action added to them, are used on machines for the purpose of removing or keeping the detrimental film from building up on the commutator. These brushes are usually few in number and are spiraled around the commutator in order to wipe the entire surface of the commutator, to an extent to keep the film from building up to a point where commutation or brush wear is adversely affected.

Cleaner brushes have no place on electric machines that are property designed and built, that are used within their designated ratings, that are fitted with the correct brush grade, that are satisfactorily installed and that are not operated under abnormal atmospheric conditions. If any one of these factors is ignored, cleaner brushes may be the economical way to mechanically remove the carbon smut laid down by a brush, because it is of poor quality or has been abused by an improperly designed or built machine, or because it has been installed incorrectly, or because of adverse loading or operating conditions. Cleaner brushes may also remove the undesirable films produced by hydrogen sulphide or other gases in the air, providing these filming gases are not too concentrated. In many contaminated industrial atmospheres, the use of cleaner brushes is not economical, because of their rapid abrasion of the copper of the commutators. In some cases, resin bonded grades have been substituted. This type of brush usually lays down a jet-black film which protects the copper from corrosive gases. The film seems to be composed of particles of brush dust bonded together and to the commutator, by a resin or varnish which may be formed from the brush bond (this may be Bakelite or other synthetic or natural resin) by a mechanism previously suggested in this paper. Unfortunately, the film is frequently high in resistance and must be removed from time to time if satisfactory service is to continue. The one big difficulty with cleaner brushes, is to secure a balance between the scouring action of the cleaner brushes and the formation of the undesirable film on the commutator. A solution is a cut and try proposition, and it is further complicated by a variation in the rate of build up of the film, which depends upon surrounding conditions, which may vary from time to time and upon the loading of the machines, which is usually not constant.

A Controlled Ventilating System

Figure 1, is a sketch of a turbogenerator exciter with an enclosed ventilating system installed in an atmosphere which has contaminating gases. A shaft mounted fan circulates the cooling air as indicated by the dotted lines of air flow. The air, discharged from the fan, first passes through a mechanical air filter to remove any carbon dust of worn brushes or other dirt that might get into the system. A water cooled heat exchanger removes the heat losses from the cooling air. The cooled air then flows back into

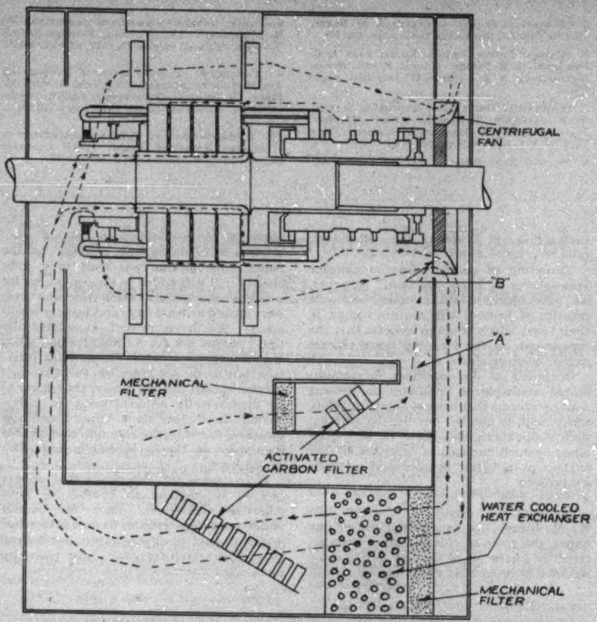

Figure 1—Turbogenerator exciter with recirculated ventilating system using mechanical filter, water cooled heat exchanger and activated carbon filter, with make-up air mechanically and chemically cleaned

the rear end of the exciter for again cooling the unit. Half of this air, leaving the cooler, passes through activated carbon cleaners which take the contaminants from that air. The activated carbon filter is more effective with cool air and is, therefore, located so that the air passes through it after passing through the cooler. The other half of the air passes through a restricted area, having the same pressure drop as that of the air passing through the activated carbon cleaners. Since the total air in the enclosure of the system is recirculated several times a minute, the entire volume of recirculated air is thus cleaned half as many times as the air is recirculated per minute. Such a scheme permits the air being effectively cleaned by the activated carbon at a velocity within the capacity of the cleaner and without requiring too large a cleaner installation.

Since it is not necessary, nor very practical, to make the enclosure vacuum tight, there will be some leakage of air out of the system at slight openings in the structure and duct system where the air pressure within is above the surrounding atmosphere and a corresponding volume of air leakage into the system at other points where the pressure is below atmosphere. These volumes are, of course, equal. By providing a definite opening into the system at point (A), which is adjacent to the inlet to the fan at point (B), where the pressure is the lowest value, all air leakage into the unit will occur through the opening at point (A), which is essentially at atmospheric pressure since the system is open to the atmosphere through a small filter there and all other points within the system will be above atmospheric pressure by an amount equal to the fan pressure, less the pressure drop in the system caused by the restriction of the air flow in the ducts and structure, at any point. Thus, any openings or cracks in the ventilating system will result in an air leakage outward and not inward. By installing a mechanical filter and an activated carbon filter in this intake opening to the ventilating system, any outside air going into the system, will be cleaned and freed of contaminated atmospheres. Such a system will operate continuously, essentially free of dirt and contaminating gasses that are harmful to successful commutation, from the standpoint of commutator surface film.

Conclusions

Commutator surface film conditions exert a large influence on the successful operation of a direct current machine from the standpoint of commutation. Duplicate machines of the same design, built on the same order in the factory, each successfully passing the manufacturer's tests, may have entirely different performance in the field. While loading conditions will have a pronounced effect frequently, the variable performance of identical machines is due to the surrounding atmospheres, under which the machines have to operate.

At the present time relatively little is known of the surface films themselves produced on commutators during operation under adverse conditions. The detrimental effects produced are recognized, but complete solutions in general for overcoming these troubles are not yet available. Machines operating under such conditions in many cases still have to be nursed along by giving attention to the commutator surface, either by the use of scouring brushes, grinding the commutator from time to time or installing protective ventilating atmospheres. The problem has also been attacked from the standpoint of producing brushes inherently designed or chemically treated during production to react with the film, supplying in some cases something missing from the atmosphere (as in the case of airplane generators) or producing a reaction which will permit the brushes to ride the film mechanically satisfactory and chemically successfully, so that acceptable commutation will result.

The authors want to point out that most commutating machines go into satisfactory service, with a minimum of commutator and brush maintenance. This paper has dealt, primarily, with those problems which are out of the ordinary; most of which come in the operating field alone and not in the design of the machine or the structure of a standard brush. Out of these troubles will come modifications in the design of the machines and development in the chemistry and processing of brushes, which will provide satisfactory operation under the present adverse conditions.

Discussion

F. M. Scott (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): The fact that small amounts of chlorine immediately improved the commutation on a machine that was sparking apparently from the effect of hydrocarbon vapors was indeed surprising.

Although the authors are familiar with the effect of chlorine on commutator films it may be worth noting, particularly on this subject, the effect of chlorine on commutators. We have found that chlorine even in very small amounts will increase the brush friction greatly. It can be observed readily that the film on a commutator will be streaked almost immediately when a large amount of chlorine is drawn across a commutator. Selective commutation often results, and a brush and its connections are overloaded when the brush breaks through the film. If the surface is not corrected such action will sometimes burn off the pig tails.

Threading of commutators in chlorine atmospheres is very common. However, we have observed that usually only one polarity of brushes will contain copper in their faces, which tends to indicate that the copper got on the faces by some process similar to electrolysis.

Operating of d-c machines in contaminated atmospheres continues to present many problems that are not solved satisfactorily, and as pointed out by the authors, such applications may have to be nursed along by such methods as described by the authors until better brushes and methods are evolved.

H. M. Elsey: As we pointed out in our paper, the trace of chlorine must have altered the character of the film on the commutator in order that commutation should improve. As we pointed out in the verbal discussion following the delivery of the paper, the chlorine was used very judiciously. It was added to the cooling air for a few seconds only at each trial and these were spaced at least days and usually weeks apart. We have proved experimentally that chlorine does cause high friction when it is present at a brush commutator interface, but we do not know whether this high friction caused the bad film on the copper to be mechanically abraded away in a few seconds or whether the chlorine chemically attacked the objectionable film and altered its nature so that a desirable oxide film would form.

It has been our experience that copper picking is common to brushes of both polarities. Moreover, since we cannot understand how electrolysis can take place in the absence of an electrolyte, we believe that copper transfer must take place by some other mechanism than electrolysis.

Methods for Determining the Effect of Contaminants on Electrical Insulation

SERVICE experience with electric apparatus has indicated that in many cases the presence of "contaminants" has contributed to the failure of electrical insulation. In the category of contaminants are included moisture, salt, oil, carbonaceous materials, and dust. Such contaminants may adversely affect both the physical and electrical properties of electrical insulation.

The General Electric Company under contract to the Bureau of Ships, United States Navy Department, has undertaken a program to develop laboratory test methods suitable for determining the effects of contaminants on electrical insulation. It is apparent that such tests to be significant must be applied to insulating materials in the form in which they appear in actual apparatus. Consequently it is best to develop test samples which consist of insulating materials in combination and which are characteristic of the combinations found in actual apparatus. This approach to the insulation problem has been described by one of the authors.[1]

It may be desirable to include this approach to the problem of writing new material specifications. There are two types of specifications for electrical insulating materials in common usage today:

1. *Material Quality Control Specification.*

Specifies tests on standard specimens and properties of the insulating material as manufactured, to determine that it is of the same quality as material previously found satisfactory by tests on the electric equipment in which it is used.

2. *Equipment Specifications.*

Specifies tests on and properties of the insulating materials indirectly by stipulating tests on and properties of the complete electric equipment in which the insulating materials are used.

It would be of obvious advantage to both insulating material and electric equipment manufacturers if means existed to predict, in advance of tests on the electric equipment itself, that the insulating material would be satisfactory in that equipment.

Material quality control specifications alone do not serve this purpose adequately. The principal reason for the inadequacy is the fact that insulating material quality control tests are conducted, and properties determined on the material as manufactured, whereas in the actual equipment such materials are used in combinations where design and construction factors play important roles not completely represented in the material quality control tests and properties.

There exists, therefore, a need for an additional type of specification.

3. *Simulated Component Specification.*

To determine the suitability of insulating materials in advance of tests on the complete equipment. This type of specification would give the tests to be conducted and properties to be determined on combinations of electrical insulating materials in a form simulating the design and construction in which the combination would occur in the electric equipment.

The purpose of this paper is to discuss the progress toward the development of test methods and synthetic contaminants suitable for evaluating the effect of contaminants on electrical insulation. The tabulated data in this paper is shown only to illustrate the type of information which can be obtained by the test methods developed, and to indicate the number of variables which may be involved. It is hoped that the success reported will serve as an incentive to the initiation of additional related programs by interested laboratories, so that eventually it will be possible to standardize on methods of tests which can be used to evaluate the suitability of insulating materials.

The Choice of Contaminants

In Navy applications a wide variety of contaminants may be deposited upon the electric apparatus. The following were considered to be most likely to occur in service.

1. Moisture—high humidity, leaking steam, mist, fog, and water.
2. Salt—salt mist, salt spray, or even salt water immersion.
3. Oil and gasoline—fuel, lubricants, and so forth.
4. Carbonaceous particles—soot and smoke from the stacks, and so forth.
5. Dust and dirt—suspended airborne soil, organic debris, and so forth.

To check these suppositions, a careful examination of the dirt scraped from representative surfaces on board ship was carefully examined and shown to contain at least the following: carbonaceous particles; lint; silica; clay; electrolytes (probably salt); and hydrocarbons (probably oil).

An enlargement of this contaminant is shown in Figure 1. Extraction and conductivity tests indicate that a relatively large proportion of oil, lint, and electrolyte is present.

It is obviously impossible to simulate in a test program the wide range of composition and character possible in each type of contaminant as it occurs naturally. In fact it is actually desirable to arrive at

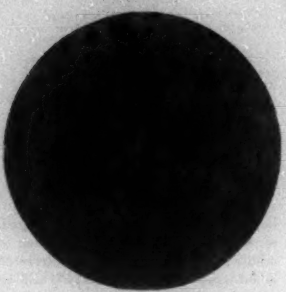

Figure 1. Dirt collected from insulation surfaces on shipboard

a definite and controllable formulation so as to permit reproducibility of test results. Moreover, the infinite variety of ways in which the contaminants may actually be deposited cannot be reproduced in tests, and an arbitrary method of applying the contaminants must be developed. However, the arbitrary materials and methods developed must be as representative as possible of actual service conditions with a tendency to emphasize the combinations and methods which produce the greatest deterioration. The development of the contaminants and methods of application actually has been carried out essentially by a process of "backing and filling"—the results of the tests on the physical and electrical properties of contaminated insulation with arbitrary contaminants has led to the formulation of different contaminants which in turn were evaluated electrically and mechanically. It is difficult and unnecessary to describe this study in chronological order but the approach and results will be described in the following sections.

Spreading of Liquid Contaminants—Contact Angles

At the beginning of the program it was apparent that the spreading of the liquid contaminants and the degree to which they "wet" various insulating surfaces should be important. To study this effect the contact angle was studied. Several such drops and their contact angles are shown diagrammatically in Figure 2. Contact angles for a number of liquids on different types of insulating surfaces are listed in Table I. A study of the relative angles for various liquids on different surfaces leads to a number of observations:

1. The contact angle of fuel oil is relatively small compared to water and salt water.
2. Number 1 fuel oil (kerosene) usually has a smaller contact angle than the more viscous oils, but this is not always the case. Apparently viscosity is not necessarily a controlling factor in determining the contact angle. Further reference to Table I will be made later in discussing the effect of liquid contaminants on physical properties.

Table II. Contact Angles

Distilled Water on Powdered Contaminants

	Adherent Liquids		
Contaminants	Turbine Oil (New)	Turbine Oil (Oxidized)	Nona-ethylene Glycol
Carbon black	131	125	0
Clay	0	0	0
1 part carbon black 5 parts clay	66	66	0
1 part carbon black 1 part clay 5 per cent salt	119	114	0

The relatively low contact angle for oils indicate that they would be the most likely to spread across a clean insulating surface and provide a base to which solid contaminants might adhere.

Table I. Contact Angles

Liquids on Various Insulation Surfaces

	Average Contact Angle						
Insulation Surface	Distilled Water	Tap Water	Sea Water	Con. Salt Solution	Turbine Oil	Gear Oil	Number 1 Fuel Oil
Short oil pigmented alkyd varnish air dried	75	70	69	71	5	11	5
Short oil pigmented alkyd varnish baked 6 hours at 160 degrees centigrade	79	76	78	79	5	10	5

Various methods of applying oil to the surface have been investigated; dipping in the oil or in the oil dissolved in solvent, vaporization, and condensation, spraying and atomizing, and simple smearing with a paper towel "wet" with the oil. Surprisingly the most uniform results were obtained with the simple smearing and this method has been adopted for most of the work.

Various methods of applying powdered solid contaminants to the oil coated surface have also been tried. In the method finally adopted, the powdered contaminant is dusted on the sample with a simple garden-type duster until the excess no longer sticks to the surface.

In service, moisture probably condenses on such dirty oily surfaces. The degree to which the condensed water spreads should affect the electrical characteristics.

Contact angles for water on various contaminants are listed in Table II. The contact angles of water on carbon black applied over an oily surface proved to be so high that an attempt was made to

find a liquid which would provide adherence for the carbon particles and at the same time permit water to spread over the surface. Oxidized oil proved to be a small step in the right direction. Since it is difficult to reproduce the oxidized oil, a liquid with a definable composition was sought. Glycerine and several other liquids were tried without success. Finally nonaethylene glycol was found to combine the ability to stick carbon particles to surfaces and simultaneously to permit water to spread over the surface.

These observations of the spreading of liquid contaminants were used as a guide in developing the contaminants used for producing the physical and electrical deterioration described in the following sections.

Effect of Liquid Contaminants on Physical Properties

Only the liquid contaminants have been used in studying physical properties since it was believed that the solid contaminants could have relatively little, if any, effect. After trials with various methods of applying the liquid contaminants, total immersion in the liquid (hot or at room temperature) was adopted for most of the work as the easiest, most uniform, and in most cases, the most severe method. However, for the more volatile oils and fuels, results indicated that the vapors from the hot liquid in some cases might produce greater deterioration than immersion. Consequently, a number of samples also were tested in this way.

Four physical properties listed below were expected to be most affected by liquid contaminants.

1. Dimensional stability.
2. Strength (tensile, compressive, shear, and so forth.)
3. Plastic deformation and creep.
4. Abrasion resistance.

Dimensional change of solid insulating materials (such as plastics) exposed to moisture and water immersion have been studied in a number of investigations. The tensile and other strength characteristics of plastics after moisture exposure also have been studied. In view of this prior work, it seemed unnecessary to repeat such measurements. However, no measurements on insulating varnishes had been reported.

To study the strength characteristics of insulating varnishes, a varnished, magnet wire helix shown in Figure 3 was used. (The sample meets the objective of insulating materials in combination.) The tensile forces required to separate the turns of the helix before and after exposure to the contaminant are listed in Table III. It is of interest that exposure to the contaminant usually increased the bond strength. The helix bond test apparently evaluates a combination of the following physical properties:

1. Tensile strength of the varnish.
2. Shear strength of the varnish.
3. Adhesive strength of the varnish to the wire.
4. Ability of the varnish to elongate slightly.

It is probable that the liquid contaminants plasticize the varnish slightly so as to increase the helix bond strength.

To investigate the plasticizing action of the liquid contaminants, the cable coil sample[3] was used. This sample is made in the form of a concentric 7-strand cable of 0.032-inch insulated magnet wire with very low twist (1/3 turn per inch). Long lengths of the cable are dipped in varnish and baked or air dried. The cable is then

cut to a 4-inch length, supported at each end, and a load applied as shown diagrammatically in Figure 4. The deflection, five seconds after applying the load, is called the deformation, and the incremental deflection after an arbitrary two minutes, is called the creep. At the end of two minutes, an increased load is applied and the deformation and creep again determined. Table IV lists values of deformation and creep for samples before and after exposure to liquid contaminants. These results show a wide divergence in results for different varnishes and contaminants, and there were some differences between different magnet wire insulations. The cable coil sample and the deformation and creep test seems very suitable for determining the plasticizing action of liquid contaminants on varnish treated structures. Solid dielectrics such as plastics cut into rectangular bars also can be evaluated with the deformation and creep test as shown by the results in Table V.

A number of abrasion tests were tried without notable success in an attempt to evaluate the effect of contaminants on a variety of insulating materials. The most useful of the abrasion tests for this purpose has been described previously.[3] The carboloy washer abrasion test is shown in Figure 5. Two and a quarter turns of the cotton, asbestos, or glass fiber tape are wrapped about the 3/8-inch rectangular brass bar, fastened with small copper wires and varnish dipped and baked. The bar is rotated under the carboloy washer until the varnish tape abrades sufficiently to permit electrical contact between the washer and bar which stops the driving motor. Table VI compares abrasion resistance before and after immersion in contaminants. The most significant comparisons are obtained with varnished glass fiber tape, apparently because the glass fiber in itself has relatively low abrasion resistance.

Effect of Contaminants on Electrical Properties

In order to survey the effect of contaminants on electrical properties, simple rectangular plastic samples with bolts and washers for electrodes were used, Figure 6. After the first measurements of surface breakdown voltages were made, it became apparent that with either short time or step by step tests, the current flowing at the low voltage tended to dry the surface and prevent breakdown. To overcome this problem, a new technique for making surface breakdown tests was developed as follows:

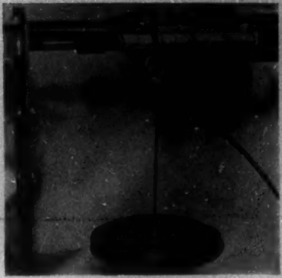

Figure 5. Carboloy washer abrasion test

1. Ten samples are used.
2. One sample is subjected to a short time breakdown test.
3. A voltage (125, 250, 500, 750, 1,000 1,300, 1,600, or 2,000) one step below the short time breakdown value is applied abruptly to three samples for five minutes and the number of failures recorded.
4. If two or three failures are obtained in Step 2, then three samples are subjected to a voltage one step below that of Step 2.

   If none or only one failure is obtained in Step 2 then three samples are subjected to a voltage one step above that of Step 2.
5. Dependent on the results obtained in Step 3, the three remaining samples are subjected to a higher or lower voltage step with the object of obtaining a voltage range—at the lowest voltage none or a maximum of one sample failed, at the highest voltage three or a minimum of two samples failed.

Table VII gives ranges of surface voltage breakdown for different contaminants under different humidity conditions. These results indicate that the effect of contaminants on surface breakdown is quite complicated. The choice of contaminants to give comparative results on different materials is restricted as outlined below:

1. The liquid used to supply adhesion for the solid contaminants should wet the solid

contaminant and also be wet by water (nonaethylene glycol).

2. A carbonaceous conducting contaminant is required.

3. A powdered contaminant such as clay is required to increase the voltage breakdown to a value sufficient to permit comparison (carbon particles alone result in too low a surface breakdown voltage to permit comparison).

4. At relative humidities less than 100 per cent an ionizable contaminant (salt) is required to obtain surface failures at less than 2,000 volts. (Salt is best added by making a water paste with the carbon black and clay followed by drying and subsequent powdering in a ball mill.) The characteristics of the liquid contaminant also are important in this respect.

A contaminant system, such as described before, has been applied to samples designed to represent a varnished magnet wire winding. These samples are shown in Figure 7. A magnet wire is wound on a wooden core ($2^1/_4$ by 3/4 inches) in two cross-wise layers using 0.032-inch wire. The top layer is wound with a regular cross-over pattern so that there are two crossovers between each set of electrodes. The electrodes are narrow strips of silver paint spaced at 1/2-inch intervals. Lengths of braided 0.010-inch copper wire are wound around the samples over these electrodes and as support for the samples in the humidity box. Breakdown voltages between silver paint electrodes on the varnished magnet wire samples are compared for different varnishes and wires in Table VIII. A study of these results leads to at least two interesting observations.

1. Surface breakdown of contaminated surfaces is affected by the kind of varnish.

2. Surface breakdown is affected by the nature of the underlying magnet wire insulation as well.

Summary and Conclusions

A number of methods have been developed for evaluating the deteriorating effect of contaminants on both physical and electrical properties of insulating materials. Suitable contaminants have likewise been developed. The results bear out the need for samples which combine insulating materials in a manner similar to that in which they are actually used. For example, the surface breakdown of a contaminated varnished magnet wire sample depends on both the nature of the treating varnish and the type of magnet wire used. It is apparent that tests on the separate components could not provide the significant information obtained with the composite sample.

The large number of factors which enter into such evaluations is most striking. In consequence, the development of significant and useful material specifications covering the effect of contaminants on insulating materials appears to be difficult. It is likely that the methods described will be most useful at first in carrying out evaluations, which it is hoped may serve as a guide to the design engineer in his choice and use of insulating materials. Additional work is being done to learn more about the problem, eliminate unnecessary variables, and simplify tests. At the same time, results with methods described are being

Discussion

A. T. McClinton (Naval Research Laboratory, Washington, D. C.): It is interesting to find that more people are now thinking in terms of evaluating the materials going into a piece of electric apparatus for its merits. This practice, which has long been recognized by a few, will lead to a more thorough understanding of the limitations in the design of equipment. It will not leave the engineer fumbling around in the dark wondering just how far he can go before he has approached or exceeded the design limitations.

Insulating materials are one of those components used in equipment about which so little is really known regarding its limitations and applications. Engineers have been working for years with specifications on spacing of live parts without any knowledge of the validity of those specifications nor how they were derived. The only check the engineer had on his design was the usual insulation tests plus service experience, neither of which informed him of the procedure he should follow in attempting to improve his design.

This paper, which presents one interesting approach to the problem, is of value in that it attempts to eliminate some of the unknown factors. There may be considerable disagreement with the techniques employed, and the numerical values obtained by the investigators, however, the purpose and ultimate goal is certainly of great importance. Its value will be greatest if it can cause others who are doing or have done similar work to publish their results.

The writers of this paper have commented on the desirability of approaching service conditions in the preparation of test procedures. This technique is unquestionably the best. However, there are actually two conditions that should be fulfilled in preparing test codes. One of these is as mentioned, namely, to simulate service conditions as nearly as possible. The second and of equal importance is to use a technique that can be duplicated readily by other laboratories. Unless this is done, obviously the procedure is of questionable value. There is considerable doubt as to how well the method of applying the contaminant, used by the authors, can be duplicated. The desirability of maintaining close control of the quantity of contaminant is demonstrated by the results in Table VII.

There are two questions concerning the procedure used, the answers to which may be of interest. These are:

1. What is the quantity of contaminant deposited per square inch of surface area?
2. Was the nonaethylene glycol used for any other purpose than as a wetting agent to provide uniform distribution of water over the surface of the test sample?

It is noted that complete surface breakdown resulting from one surge has been the technique employed in determining the electrical property of the insulation when contaminated. Certainly this is a simple test procedure and may give comparative data on different insulations with various contaminants. However, such a procedure does not consider all the factors, one of which is the effect on the breakdown voltage of repeated surges at lower voltages.

Concerning the results presented in Table VII, it would be of interest to know whether the authors have made sufficient tests to know how this data compares with that for other insulating materials. Also, information as to how quickly the breakdown was noted after application of the voltage in Step 3 might help the reader to understand some of the complexities of the effects of contaminants on surface breakdown. The statement has been made in the paper that "An ionizable contaminant (salt) is required if surface failures are to be obtained at less than 100 per cent relative humidity." This statement does not appear to be in agreement with the results presented.

K. N. Mathes, L. E. Sieffert, H. P. Walker, R. H. Lindsey: In reply to McClinton's specific questions, a uniform procedure has been developed for the application of the contaminants described which we believe will give reasonably reproducible results. The actual amounts of contaminant have not been measured directly, but insulation resistance measurements are being used to serve as an indication and control. The nonaethylene glycol used must "wet" the sample and the solid contaminant as well as providing a means for water to spread uniformly over the contaminated surface. In more recent work we have been able to obtain even more uniform results by using a combination of polyethylene glycol and glycerine.

We agree that the repeated application of voltage is an important service consideration and have made some preliminary investigations of this effect. Application of voltage tends to dry out the moisture at the surface of the sample. If sufficient time between applications of voltage is allowed so that the surface can soak up moisture, then a lower surface breakdown value will be obtained. For a thorough understanding of the problem the effect of repeated voltage applications should be investigated. It is believed, however, that the values after a single application of voltage give results which permit a comparison of materials.

Very recently quite a number of different insulating materials have been evaluated. Different surface breakdown values are obtained for different materials which indicates that the nature of the material is important. Most of the surface breakdowns occurred within 30 seconds after application of voltage, although a few were obtained throughout and even at the end of the 5-minute period of voltage application. Physical examination of the samples lends support to the theory that a progressive degradation occurs which is in conflict with the drying out that occurs at the same time. Breakdown occurs only when the rate of progressive deterioration outstrips the drying out which occurs simultaneously.

Failures at less than 100 per cent relative humidity can, of course, occur without ionizable contaminants if a sufficiently high voltage is applied. In the work described, however, voltages have been limited to 2,000 volts and within this range failure does not occur until an ionizable contaminant is present.

We wish to thank McClinton for the insights shown in the analysis of our work. Such suggestions are helpful in our program.

Solid Short Circuit of D-C Motors and Generators

T. M. LINVILLE
FELLOW AIEE

H. C. WARD, JR.
ASSOCIATE AIEE

Synopsis: In this paper the current of d-c machines on solid short circuit is expressed in terms of constant impedances similar to x_d' and x_d for synchronous machines. The outstanding advantage of this new result is that any number of d-c machines may be included in a network, with or without connection of batteries, rectifiers, or other machinery, and calculations may be made using a network analyzer, d-c calculating board or numerical calculation. The current in any machine, the total fault current, and so on, can be determined. Equations are given for d-c machines which are similar to the well-known equations for synchronous machines. Equations are given for the transient and steady-state resistances and for the decrement factors. The latter factors determine the rise and subsequent decline of current. Direct and simple expressions are given for the maximum rate of rise of current and for the maximum or peak value of current. Although design data is required for reliable calculations, useful preliminary estimates of current can be made using no data other than the resistance of the machine windings and a few dimensions which can be obtained from simple inspection of the machines. For this purpose, generalized values for design constants are given in the nomenclature.

IN A PAPER presented in 1946,[1] an analysis of short-circuit phenomena in d-c machines was described and formulas were derived for the current and torque. These formulas were expressed in terms of impedance which was variable with line current because of the influence of magnetic saturation in the armature teeth. Therefore, although the formulas were satisfactory for the case of one machine short circuited alone, when a number of machines were connected in a network the formulas were not suitable for simple calculations. Thus, there has been a need to derive the formulas in terms of constant impedances. Additional work has shown this can be done as described in this paper. Results are given in the following sections followed by an explanation of their derivation.

Short-Circuit Currents

Similarity between the new formulas and those for synchronous machines will be noted.[2,3] For a d-c machine the current on short circuit is

$$i_a=\frac{e_0}{r_d}-\frac{e_0}{r_d'}\epsilon^{-\sigma_a t}+e_0\frac{r_d-r_d'}{r_d r_d'}\epsilon^{-\sigma_f t}\text{ per unit} \tag{1}$$

where e_0 is the electromotive force existing in the machine just previous to short circuit (terminal voltage plus or minus winding and brush drop), r_d is the steady-state effective resistance of the machine, and r_d' is the transient-state effective resistance.

These quantities are all per unit. σ_a is the armature circuit decrement factor for the machine, and σ_f is the field circuit decrement factor.

The maximum short-circuit current is

$$I_a'=\frac{e_0}{r_d'} \tag{2}$$

The initial and also the maximum rate of rise of current is

$$\frac{di_a}{dt}=\frac{\sigma_a e_0}{r_d'} \tag{3}$$

since other terms in the derivative of equation 1 are negligible.

The field current is

$$i_f=\frac{e_0}{n_0}\left\{1+\frac{r_x'}{r_d' n_f}(\epsilon^{-\sigma_f t}-\epsilon^{-\sigma_a t})\right\}\text{per unit} \tag{4}$$

where r_x' is the per-unit transient-state compounding resistance, taking into account the effect of armature current on generated electromotive force; and n_f is the leakage flux coefficient for the field winding, ratio of total field flux linkages minus field linkages from flux-generating armature electromotive force to field linkages from flux-generating armature electromotive force.

Transient Resistances

The transient effective resistance is

$$r_d'=r_w+r_b'+r_x'+r_e \tag{5}$$

where r_w is the resistance of the windings, r_b' is the transient resistance of the brush contact, r_x' is the transient compounding resistance, and r_e is the resistance external to the machine if any; all quantities are per unit.

The resistance of the brush contact is derived in the previous paper as follows[1]

$$r_b'=E_R b\left(\frac{\epsilon^x+1}{\epsilon^x-1}\right)+V_c \tag{6}$$

where E_R is the average per-unit reactance voltage per armature coil at rated full-load current and at speed at which machine is short-circuited, b is the width of brush contact face in commutator segments, V_c is the normal per-unit full-load brush and brush contact voltage drop, and

$$x=\frac{E_R b}{V_c}$$

The effective compounding resistance, r_x', was treated in the previous paper as a variable.[1] It is the factor which measures the change in electromotive force between the initial electromotive force just before short circuit and the electromotive force existing when maximum armature current is reached. The new result for r_x'

The authors wish to thank A. G. Darling and R. G. Rhudy for their assistance in making this paper possible and for the calculations given in Table I.

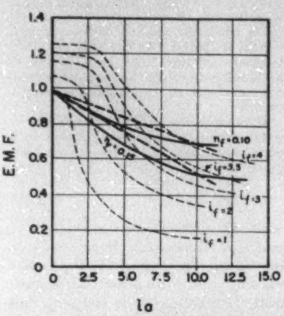

Figure 1. Relation between electromotive force, armature current, and field current

as a constant is, for machines without pole-face windings

$$r_x' = \frac{10 n_f e_o + n_f(K_1 + 10K_2)(10K_3 n_o - e_o)}{100(n_f + K_2) + 10K_1} \quad (7)$$

where

$$K_1 = \frac{p_p \phi_t}{p_a M_{a1}}$$

$$K_2 = \frac{C_s C_d K_\lambda g K_t}{0.85(g + d_s)} = \frac{1.25 g K_t}{g + d_s}$$

$$K_3 = \frac{(b \pm 2b_s) P M_{a1}}{B}$$

The symbols in these formulas for K_1, K_2, and K_3 are given in the nomenclature. ϕ_t on which K_1 is dependent is the flux in per unit determined by multiplying the average cross section of the armature teeth in square inches by the number of teeth in a pole arc by the intrinsic saturation density of 123,000 maxwells per square inch and dividing by unit flux in maxwells.

When a machine has pole-face windings and there is no serious distortion of flux in the main pole shoes and consequently no extreme saturation of the armature teeth, equation 7 becomes

$$r_x' = \frac{K_3 n_f n_o}{1 + n_f} \quad (8)$$

Steady-State Resistances

The steady-state effective resistance for separately excited machines is

$$r_d = r_w + r_b + r_x + r_e \quad (9)$$

where, for machines without pole-face windings

$$r_x = \frac{10e_o + n_o(10K_3 - I_{fo})(K_1 + 10K_2)}{100} \quad (10)$$

For a separately excited machine with pole-face windings

$$r_x = \frac{e_o + n_o(10K_3 - I_{fo})}{10} \quad (11)$$

The brush and brush contact resistance for either type of machine is

$$r_b = E_R(1 - E_c) b \left(\frac{\varepsilon^x + 1}{\varepsilon^x - 1} \right) + V_c \quad (12)$$

where

$$x = \frac{E_R(1 - E_c) b}{V_c}$$

and E_c is the estimated ratio, under sustained short-circuit conditions, of actual interpole field strength to field strength if no saturation occurred.

Decrements

The decrement factor σ_a for the armature circuit is

$$\sigma_a = \frac{r_d' 2\pi f}{C_x} \quad (13)$$

where f is the frequency of the machine in cycles per second at rated base speed, equal to number poles times revolutions per minute divided by 120, and C_x is the inductance coefficient. For machines without pole-face windings, C_x is about 0.6. For machines with pole-face windings, C_x is about 0.15. All factors in equation 13 are per-unit quantities except for frequency. The inductance L_a should be calculated from the dimensions of the windings and magnetic circuits whenever possible. Values given for C_x are preliminary and are subject to change when more test data is obtained. At best, C_x is an average coefficient and will vary quite widely between particular machines and between particular conditions of saturation.

Saturation will change the effective inductance, L_a, greatly. For example, when a machine without pole-face windings is excited at full rated excitation, it usually is operating above the knee of the saturation curve, and C_x, therefore, may be as low as 0.15. This is because in these machines a large part of the inductance is caused by flux in the main pole air gap caused by armature excitation. When a machine of this type at full excitation is excited above the knee of the saturation curve largely because of saturation in the armature teeth, the effective inductance from flux in the main pole air gaps will be reduced about in proportion to the ratio of the slope of the saturation curve at full excitation to the slope of the air-gap line, that is, the slope without saturation.

The decrement factor for the field circuit is

$$\sigma_f = \frac{r_f}{L_f} \quad (14)$$

where r_f is the resistance, which is simply the ratio of exciter volts to excitation amperes, and L_f is the inductance of the circuit, which is the flux linkages per ampere of the field coils times the number of coils in series times 10^{-8}. Saturation will change the effective value of L_f. Correction for it must be made. The simplest method is to reduce the flux linkages per ampere resulting from air-gap flux in proportion to the ratio of the slope of the saturation curve at the actual field excitation to the slope without saturation (slope of air-gap line).

Current Rise

It should be understood that the paper is concerned with the effect of saturation from two different causes. In the foregoing sections saturation existing before short circuit as a result of field excitation has been discussed. Now, in plotting the rise of current against time, account must be taken of the increase in σ_a caused by saturation resulting from the heavy load current.

To do this, the line given by equation 3 should be drawn remembering that, for machines without pole-face windings and with excitation before short circuit definitely above the knee of the saturation curve, C_x must be reduced to about 0.15. Assume that the current rises at this constant rate for a time interval of 0.67 σ_a seconds and thereafter goes parallel at all levels of current to equation 1 plotted with σ_a replaced by $3\sigma_a$.

This curve and the curve of equation 1 without modification can be expected to bracket the true current. The total change in σ_a during the rise in current is not likely to increase σ_a beyond $3\sigma_a$.

Per-Unit Quantities

All quantities for current, voltage, resistance, flux, magnetomotive force, and speed in the formulas are per unit, that is, each of these quantities has been divided by the corresponding base quantity. Base quantities are as follows:

V_1 = rated voltage, in volts
I_{a1} = rated full-load amperes
I_{f1} = rated full-load field amperes
$R_1 = V_1/I_{a1}$
N_1 = rated base speed
M_{f1} = field ampere turns per pole at rated voltage, rated base speed, no load
ϕ_1 = flux per pole in maxwells at V_1 and N_1

Assumptions

In our calculations, the following assumptions were made:

1. Saturation other than in armature teeth and pole-face teeth is neglected.
2. Leakage flux linkages of the field winding are proportional to field amperes.
3. Center of current in brush faces is at trailing edge of the brushes at instant of maximum current.
4. Change in commutating pole flux between instant of short circuit and instant of maximum current is negligible because of damping effects of solid steel frame, helped in many cases by solid steel poles.
5. Speed of the machine is maintained.

Discussion of Results

The calculation of sustained short-circuit current is included solely for completeness. It is not likely that machines of 250 volts and higher will reach sustained short-circuit current without flashing over or without such arcing at the brushes as to destroy the accuracy of the assumptions on which the paper is based.

It is to be expected that, in many cases, the current will be drawn out beyond the trailing edge of the brushes even at the moment of maximum current, causing measured current in cases where tests are made to be less than calculated current. To make calculations, it is necessary to fix the axis of armature reaction at some definite location, such as at the trailing edge of the brush, where the resulting error, if any, will yield a high current rather than a current lower than actual.

The use of the decrement factors requires use of good judgment in lieu of extensive calculations for inductance if the rise of current is to be plotted accurately. Otherwise, the inductance coefficient C_2 should be 0.15 for all machines with or without pole-face windings, and the current rise should be plotted as described in the section entitled "Current Rise" with the decrement factor σ_a increasing from σ_a to $3\sigma_a$.

Method and Basic Equations

For clarity and correction of the earlier paper,[1] the set of simultaneous equations whose solution gives the results presented in this paper are restated as follows.

The fundamental equation relating exciting flux, armature amperes, and field amperes is, for machines without pole-face windings

$$\phi_d' = \frac{M_f' p_p \phi_i}{M_a' p_a} + M_f' \rho \frac{\phi_1 K_1}{M_{f1}} \qquad (15)$$

where $\rho K = {}_1K_2$, as given in equation 7.

Equation 15 has two terms representing iron flux and space flux respectively. It was found necessary to divide the flux into these two components in order to take saturation of the armature teeth into account.[1] However, when there is no serious distortion of flux in the main pole shoes resulting from cross magnetization by armature magnetomotive force and consequently no extreme saturation of the armature teeth, equation 15 is not applicable. These conditions hold true in the case of machines with pole-face windings. Therefore, in this case the flux can be expressed as a function of the field-winding magnetomotive force alone as

$$\phi_d' = \frac{M_f' \phi_1 K_1}{M_{f1}}$$

This neglects all saturation, as is evident from line (*a*), Figure 2. So as not to neglect altogether the normal saturation, the saturation curve is taken as line (*b*), Figure 2, so that

$$\phi_d' = \frac{M_f' \phi_1}{M_{f1}} \qquad (16)$$

The fundamental equation relating field-circuit flux linkages immediately after short circuit to those immediately before short circuit, in accordance with the constant-linkage theorem,[4] is

$$\phi_d' + n_f \frac{\phi_1}{I_{f1}} I_f' = \phi_o(1 + n_f) \qquad (17)$$

The equation summing the voltages in the armature circuit is

$$I_a' = \frac{\phi_d' n_o}{r_w + r_b' + r_e} \qquad (18)$$

Equations 15, 17, and 18, or 16, 17, and 18, for machines without or with pole-face windings respectively, are the basic equations.

The effect of shift of the axis of armature magnetomotive force, caused by brush shift and by brush arcing, is included by replacing M_f' of the basic equations with M_d'. Assuming that brush arcing causes the axis of armature reaction to lie in line with the trailing edge of the brushes

$$M_d' = M_f' - \frac{(b \pm 2b_s) P M_a'}{B}$$

where M_d' is the net magnetomotive force in the main pole axis, M_f' is the field winding magnetomotive force, and M_a' is the armature reaction magnetomotive force. The brush shift from the polar axis, b_s, measured in commutator bars, is plus if with rotation, minus if against rotation. P is the number of poles. B is the total number of bars in the commutator. b is the brush width in bars.

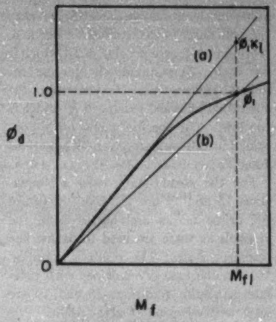

Figure 2. Saturation curve

Then, to express the basic equations in terms of the maximum armature current, I_a', and the maximum field current, I_f', the following relations are substituted

$$M_a' = \frac{M_{a1}}{I_{a1}} I_a'$$

$$M_f' = \frac{M_{f1}}{I_{f1}} I_f'$$

Each group of basic equations now can be solved for the maximum currents I_a' and I_f', obtaining results similar to those given in the earlier paper.[1] These results are complicated because the relation between armature electromotive force and armature current is not linear, as illustrated by the solid lines of Figure 1. An approximation can be made which is linear, as illustrated by the heavy dashed lines in Figure 1, by writing the change in electromotive force as equal to $I_a' r_x'$.

Then the flux, ϕ_d', responsible for electromotive force can be written

$$\phi_d' = \frac{e_o}{n_o} - \frac{I_a' r_x'}{n_o} \qquad (19)$$

where e_o is the electromotive force before short circuit, and n_o is the corresponding speed of the machine. By the simultaneous solution of equations 15, 17, and 19, or equations 16, 17, and 19 as the case may be, r_x', which is the slope of the heavy dashed lines in Figure 1, is found as a function of I_a'. However, if a specific value of 10 is assigned to I_a', the slope becomes specific as shown in Figure 1, and heavy dashed lines which are good approximations of the solid curved lines are obtained. It is apparent from Figure 1 that, for current values less than 10 per unit, this approximation will yield a value of electromotive force higher than the true value of electromotive force and, therefore, will give a value of I_a' which is too high. Correspondingly, for current values higher than 10 per unit, the equations will yield a value of I_a' which is too low. The specific values for r_x' obtained in this way are given by equations 7 and 8.

For the steady-state value r_x, equations 15 and 19 are the root equations. All prime marks are deleted from the symbols as these are used to denote the transient state. The result is equation 10. In the case of machines with pole-face windings, equations 16 and 19 are used, with equation 11 as the result.

Substitution of equation 19 in equation 18, and equation 5 into the result shows that $I_a' = e_o/r_d'$. Similarly, $I_a = e_o/r_d$. The complete current–time formula, equation 1, now can be developed. The armature current has the following components

Rise

$$I_a'(1-\varepsilon^{-\sigma_a t})$$

Decay

$$-(I_a'-I_a)(1-\varepsilon^{-\sigma_f t})$$

The time constants are so dissimilar that the components may be added together directly with negligible error, giving

$$i_a=I_a-I_a'\varepsilon^{-\sigma_a t}+(I_a'-I_a)\varepsilon^{-\sigma_f t} \tag{20}$$

Equation 1 follows when $I_a' = e_o/r_d'$ and $I_a = e_o/r_d$ are substituted in equation 20. Similarly, for the field current, the current starts with the initial current I_{fo} and has the following additional components:

Rise

$$(I_f'-I_{fo})(1-\varepsilon^{-\sigma_a t})$$

Decay

$$-(I_f'-I_{fo})(1-\varepsilon^{-\sigma_f t})$$

Adding these three components together

$$i_f=I_{fo}+(I_f'-I_{fo})(\varepsilon^{-\sigma_f t}-\varepsilon^{-\sigma_a t}) \tag{21}$$

Solving equations 17 and 19 for I_f' and substituting e_o/n_o for ϕ_o gives

$$I_f'=\frac{e_o}{n_o}+\frac{I_a'r_x'}{n_o n_f} \tag{22}$$

By putting $I_{fo} = (e_o/n_o)\ (I_{f1}/\phi_1)$ and $I_a' = e_o/r_d'$, equation 4 is obtained from equations 21 and 22 for the field current in per unit.

Conclusions

Calculations for several different types of d-c machines are given in Table I, showing that the current on dead short circuit with negligible external resistance is widely different between machines of different types and ratings. Therefore, short-circuit current cannot be determined without formulas such as given in this paper accounting for such important factors as r_x' and r_b' expressed in terms of measurable machine quantities. The authors feel sure that persons familiar with d-c machines will recognize the results given in Table I as typical of test results.

Comparison of calculations with test oscillograms in a few specific instances have shown good checks.[1] However, the rate of rise of current subsequent to the initial or maximum rate of rise is an estimate only. Also, the value for sustained current is mainly of academic interest especially in cases of high-voltage machines where flashover is more or less certain to occur. To account for the effect of changing magnetic saturation on the rise of current beyond an approximate method such as given here requires lengthy, step-by-step calculations.

Nomenclature

b = brush overlap, in segments
b_s = brush shift from polar axis, segments
B = total number of segments in commutator
C_s = air-gap slot fringing coefficient[1]
C_δ = air-gap duct fringing coefficient[1]
C_x = inductance coefficient, average value 0.15
d_s = depth of armature slot, inches
d_a = diameter of armature, inches
E_c = estimated ratio, under sustained short-circuit conditions, of actual interpole field strength to field strength if no saturation occurred. Generalized value = 0.3
e_o = armature electromotive force before short circuit, in per unit
E_R = average per-unit reactance voltage per coil at rated full-load current and at speed at which machine is short-circuited. At base speed, average value is $12n_oI_{a1}10^{-8}/d_a$ or, preferably, $5\times10^{9}lBI_cN_1n_o/V_1$
f = machine frequency at base speed, cycles per second
g = average length of main-pole air gap, inches
i_a = instantaneous short-circuit current, per unit
i_f = instantaneous short-circuit field current, per unit
I_a = steady-state short-circuit current, per unit
I_a' = maximum short-circuit current, per unit
I_{a1} = base amperes = rated full-load armature current, amperes
I_c = rated full-load armature amperes divided by number of circuits in armature winding. Number of circuits

usually is two in small machines and in medium and big machines is usually equal to number of poles

I_{f1} = base field amperes = field amperes at rated voltage, base rated speed, no load

K_1 = coefficient for flux ϕ_t. Generalized value = 0.92

K_2 = coefficient for permeance ratio Generalized value = 0.17

K_λ = pole tip flux fringing factor[1]

K_t = air-gap plus tooth ampere turns divided by air-gap ampere turns at rated voltage, base rated speed, no load

l = length of armature core, in inches

L_f = inductance of field circuit divided by unit ohms, R_1

M_{a1} = armature reaction magnetomotive force at full rated load, per unit. Representative value = 1.0

M_f' = maximum field ampere turns per pole, per unit

M_{f1} = base ampere turns = field ampere turns per pole at rated voltage, rated base speed, no load

n_f = ratio total field flux linkages minus linkages from flux responsible for armature electromotive force to linkages from flux responsible for armature electromotive force. Representative value = 0.15

n_o = speed at which machine is short-circuited, per unit

N_1 = base or unit speed = rated base speed, revolutions per minute

p_a = pole arc, inches

p_p = pole pitch, inches

P = number of poles

r_b = steady-state resistance of brush and brush contact, per unit

r_b' = transient resistance of brush and brush contact, per unit

r_d = steady-state effective total resistance of machine under short circuit, per unit

r_d' = transient effective total resistance of machine under short circuit, per unit

r_e = external resistance, per unit

r_f = resistance of field circuit, per unit

r_z = effective steady-state compounding resistance, per unit

r_z' = effective transient compounding resistance, per unit

r_w = effective total resistance of windings in armature circuit, per unit

R_1 = base ohms = V_1/I_{a1}

V_1 = base volts = rated voltage, volts

V_c = normal brush contact drop at full load, in per unit. Equals $3/V_1$ for graphitized brushes or $1/V_1$ for metal graphite brushes

ϕ_1 = base flux = flux per pole in maxwells at rated voltage, rated base speed, no load

ϕ_t = iron flux per pole, in per unit. Equals average section of armature tooth in square inches times number of teeth in pole arc × 123,000 lines per square inch divided by ϕ_1

ϕ_d' = flux responsible for armature electromotive force, per unit

ϕ_o = flux per pole before short circuit, per unit

σ_a = armature circuit decrement factor

σ_f = field circuit decrement factor, generalized value = 1.0

Discussion

F. M. Scott (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): The procedure outlined in this paper for calculating the short-circuit currents of d-c machines is a practical method, particularly when it is necessary to consider several machines in a given system. The potential short-circuit current possibilities should be considered on any system containing a number of d-c machines. Installations such as hot strip mills can have values of short-circuit currents as high as 500,000 amperes. The actual occurrence of such faults on such systems has emphasized the need for such a procedure. A knowledge of values of current that are possible will allow proper preventive steps to be taken. Such known steps now are separating the two busses to minimize the possibility of faults, sectionalizing the bus sections with high-speed circuit breakers. Further development of better circuit breakers will be required.

The results in Table I of this paper are quite typical, but, as Linville pointed out, the actual short-circuit current calculation involves the consideration of many factors. We also have found the degree of saturation affects the results appreciably. Inductance varies with the degree of saturation, and is a factor that affects particularly the time required to obtain a given value of current.

There are so many variables such as speed drop, saturation, fault resistance, and so forth, that it almost is mandatory to use such a system as that outlined by the authors. The results obtained are quite safe as they are the maximum possible, and any actual values always would be less than those calculated. Such a paper as this requires a vast amount of computation and numerous tests. I believe that additional tests and investigations would be useful so that these previously indeterminate factors can be calculated with even closer accuracy.

T. M. Linville, H. C. Ward, Jr.: Questions have been asked about the accuracy which can be expected of the results and about the dimensional correctness of several of the equations. It also has been asked whether or not the equations are applicable at any initial value of speed, voltage, and load current, and whether they are equally accurate for very small as well as very large machines. The final question asked is: can the results be developed into a generalized method for the determination of short-circuit currents in d-c systems similar to the procedure already developed for a-c systems?

Accuracy is important of course, and the authors have found that the results usually will come very close to test values. This statement applies to the maximum value of current only. On solid short circuit, the current usually is drawn out from the trailing edge of the brushes rapidly in the form of heavy arcing, followed in many cases by flashing. This causes the current to be less than calculated, so that usually it is found that the calculated current is a little higher than actual. Calculation of the rate of rise of current depends upon the calculation of the inductance of the circuit as well as the effective circuit resistance. The inductance is affected, by magnetic saturation which varies with the value of currents in the armature and field circuits. However, calculation of the initial rate of rise (the maximum rate) will be found to be accurate, because the initial inductance can be calculated accurately, taking into account the saturation caused only by field current. It is important to remember that a machine at full excitation has a faster rate of rise than a machine at partial excitation. The time constant must be corrected for field-current saturation as described in the paper.

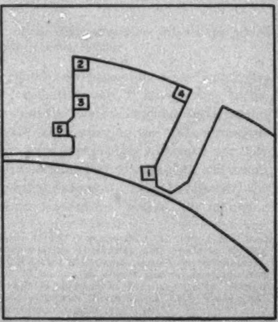

Figure 1

Care must be taken in making the calculations when a machine has a series field which is loosely coupled with the shunt field, and when a machine has a pole-face winding which gives incomplete compensation under the pole face. When the series field is loosely coupled, the formula for K_3 in equation 7 of the paper should become

$$K_3 = \frac{(b \pm 2b_s)PM_{a1}}{B} \pm k_s M_s$$

where k_s is a coefficient depending on the position of the series field, and M_s is the number of series-field ampere turns at rated full-load current in per unit. The sign of k_s is plus for differential series field and minus for cumulative series field when the machine is under short circuit. The following values of k_s are estimated for the positions shown in Figure 1 of the discussion:

Position	k_s
1	0.9
2	0.05
3	0.2
4	0.15
5	0.35

When the pole-face winding gives incomplete compensation, equation 7 should be used rather than equation 8, and K_1 should become

$$K_1=\frac{p_p\phi_t}{p_a M_{a1} k_c}$$

where

$$k_c=\frac{p_a M_{a1}-M_{b1}p_p}{p_a M_{a1}}$$

The importance of these corrections for series field and partial pole-face compensation has been shown by the results of tests made by the Naval Research Laboratory for the Bureau of Ships. Oscillograms from test are to appear in an AIEE paper, now in preparation. Their calculations checked test results closely when correction was made for a loosely-coupled series field, but did not do so using the bare formulas of the paper.

The authors undoubtedly owe an apology for not maintaining dimensional correctness of equations in which quantities are per unit. For example, equations 6 is actually

$$r_b'=E_R b\left\{\frac{\varepsilon^x+1}{\varepsilon^x-1}\right\}\frac{R_1}{V_1}+V_c\,\frac{R_1}{V_1}$$

Written this way the equation is dimensionally correct either with actual or per unit quantities. E_R is in volts per coil (volts per segment), b is in segments, R_1 is in ohms, V_1 is in volts, and V_c is in volts. r_b' is then in ohms. When all quantities are per unit, V_1 and R_1 are unit quantities. When one is substituted for each of them, the equation given in the paper is obtained. In all of the results, unit quantities have been dropped out and only per unit quantities retained.

The equations as given are applicable at any initial values of speed and voltage. n_o and e_o are fractional quantities according to the ratio of initial speed and voltage to rated speed and voltage, respectively. When there is an initial load current, I_a' and I_a are unaffected, but to make equation 20 correct, the initial load current I_o must be subtracted from I_a and I_a' in each place in the equation, and I_o must be added to the right-hand member of the equation as a new term.

The formulas are applicable to machines of all sizes.

The development of a new method often may be the start of a chain of progress and, therefore, the authors hope that calculations of a large number of machines, including all sizes and types, will be made, and that from resulting data, presented in suitable graphs and tables, it will be possible to find at a glance the maximum short-circuit current, maximum rate of current rise, and transient resistance for practically any machine whose nameplate data are known. It seems promising, therefore, that the design of machines, of bus structures, of circuit breakers, and the protection of equipment in d-c networks can be done more accurately and by substantially the same methods as have been developed for synchronous machines.

Application Engineering on Diesel-Electric Locomotives in Railroad Service

G. T. BEVAN
MEMBER AIEE

FORTY-FIVE per cent of the total operating expense of a railroad is affected by the character of motive power used. Consequently, very careful consideration should be given to the proper selection of locomotive power. From a strictly engineering viewpoint, a locomotive should be purchased as "a tool to fit the job," while from an economic standpoint, it is quite obvious that a complete cost study should be made before finally selecting the type of power.

This approach of "fitting the tool to the job" in the selection of Diesel-electric railroad power—as compared to the prior practice wherein steam locomotives were purchased and tested afterward with a dynamometer car to determine their hauling capacity—is now generally offered by the locomotive builders. This practice not only fits the correct Diesel-electric locomotive to the job, but also determines the economics involved, from an initial investment standpoint as well as from an annual operating expense comparison.

With the advent of the Diesel-electric locomotive, a new approach to train operation had to be established. The Diesel-electric locomotive can be overloaded to the point of damaging the electrical equipment if tonnage and grade conditions reduce the speed below a given continuous speed. This is not true of steam operation; a steam locomotive can be overloaded to the point of stalling without damage. It became necessary, therefore, for the Diesel-electric-locomotive manufacturer to establish a continuous as well as a short-time tonnage rating for any particular locomotive application.

Speed–distance curves enable the engineering and economic aspects of a given application to be readily understood. This graphical analysis is used as a basis for determining the fundamental application. It is the calculation of the operation of a train of predetermined size and weight at a certain speed over a given profile, in such a way that the complete running time as well as the continuous speed is obtained. A typical speed–distance curve is shown in Figure 1. From this basic information it is quite feasible to determine the economic aspect of a dieselization proposal, inasmuch as the total fuel consumption is readily obtained. The preliminary data needed to plot a speed–distance curve are:

1. Railroad profile, including rail weight, curve data, and elevation for plotting a condensed profile.
2. Employee's timetables, giving the number of stops and speed restrictions on the section under consideration.
3. Train performance data, giving information as to train size and weight in tons to be hauled.
4. Data as to equipment characteristics, such as air-conditioning, car weight, and so forth.
5. Train dispatcher's records for the period under consideration.

Before recommending a particular size of locomotive unit, it is necessary to determine the axle loading in order to permit a safe rail loading on the track structure. Excessive axle loading will cause not only rail and road-bed damage, but will result also in unsafe operation. In selecting the proper size of locomotive, the following data, giving the axle loadings permissible for different weights of rail, are helpful:

Rail Weight Pounds/Yard	Maximum Axle Load Per Pound of Rail Weight
0–60	500 pounds
61–90	600 pounds
91–152	700 pounds

For example: a 100-ton 4-axle locomotive will operate safely on 85-pound rail where the permissible loading is 85 ×600 = 51,000 pounds.

Tonnage Ratings

The next preliminary investigation is to determine the size of locomotive necessary to handle a given tonnage over the designated profile at a selected speed. Knowing the grade, curve, and train resistance and the tonnage to be hauled, the locomotive tractive effort and horsepower can readily be obtained. Let us assume a ruling grade of 1 per cent, a maximum curve of 4 degrees, a train resistance of 4.8 pounds per ton, and a freight tonnage of 70 cars at 40 tons per car. The total train resistance is the algebraic sum of the grade, curve, and train friction resistances. In this case the train resistance is 20 + 3.2 + 4.8 = 28 pounds per ton.

The continuous tractive effort of a typical single-unit 1,500-horsepower (115-ton) road locomotive, geared for a top speed of 65 miles per hour, is 42,500 pounds. Thus, knowing the locomotive weight, the required tractive effort can be derived from the following:

$$\text{Tractive effort} = \text{Train Resistance} \times (\text{Train weight} + \text{Locomotive weight})$$

or

$$\text{Train weight} = \frac{\text{Tractive effort}}{\text{Train resistance} - \text{Locomotive weight}}$$

$$= \frac{42{,}500}{28} - 115$$

$$= 1{,}400 \text{ tons (trailing)}$$

$$= 35 \text{ cars at } 40 \text{ tons/car}$$

Since one unit can handle 1,400 tons, a 3,000-horsepower 2-unit locomotive will handle the specified 2,800-ton train. The speed over the ruling grade will be 110

Paper 49-42, recommended by the AIEE land transportation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 12, 1948; made available for printing January 1, 1949.

G. T. BEVAN is in the Alco-GE Division of the General Electric Company, Schenectady, N. Y.

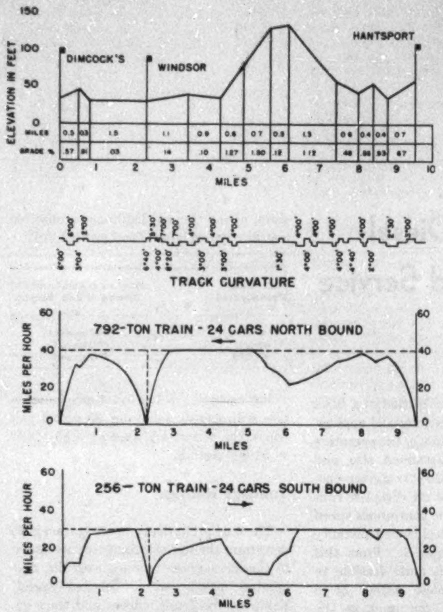

Figure 1. Condensed profiles and speed-distance curves, freight service

Alco-GE 2,000 horsepower (2-unit) locomotive. Speed restriction shown by broken lines

miles per hour, as shown on the characteristic curve for this locomotive.

Should it be desired, however, to handle a 1,400-ton train over the ruling grade at a speed between 25 and 30 miles per hour, a 3-unit 4,500-horsepower locomotive would be required. The tractive effort would be:

$$\text{Tractive effort} = 29.5\ (1{,}400 + 345) = 51{,}500 \text{ pounds}$$

This gives a speed over the grade of 27.5 miles per hour as noted from Figure 2. In this case, the running adhesion is comparatively low allowing minimum wheel slipping. The adhesion factor for a locomotive operating under these conditions is:

$$\text{Adhesion factor} = \frac{\text{Required tractive effort}}{\text{Weight on drivers, pounds}} = \frac{51{,}500}{345 \times 2{,}000} = 7.5 \text{ per cent}$$

The maximum running adhesion value with a dry, clean rail in good condition should not be over 20 per cent. Rail that is wet or in poor condition will necessitate the use of a lower adhesion value.

On relatively short grades over a rolling profile, the kinetic energy accumulated running down grade can be used to assist the train over the next ascending grade. After the momentum has been completely used up, it may be necessary to demand a locomotive output considerably higher than the continuous rating of the traction motors for a short time until the summit of the grade is reached. In this case, a short-time or overload rating may be used, provided, of course, that the adhesion factor of 20 per cent is not exceeded.

As an example, consider a rolling profile in which a ruling grade of one per cent for two miles is such that momentum operation could be employed. Assuming the curve resistance at one pound per ton and the train friction resistance at four pounds per ton of train weight, the continuous tonnage rating with a 4,500-horsepower (345-ton) locomotive would be:

$$\text{Trailing tons} = \frac{\text{Continuous tractive effort}}{\text{Train resistance}} - \text{Locomotive weight}$$

(Train resistance = Grade resistance + Curve resistance + Train friction resistance)

$$= \frac{127{,}500}{20+1+4} - 345 = 4{,}755 \text{ tons.}$$

Assuming 50-ton cars, this equals a 95-car train. Since the grade is only two miles in length, the short-time overload rating up to the slipping point (20 per cent) could be used. In this case, the momentum of the train would be considered run out in a train length or approximately 4,280 feet (95 cars × 45 feet length per car). Therefore, a distance of 6,280 feet or 1.19 miles is left to climb, in which the short-time rating could be used to advantage. At 20 per cent adhesion the tractive effort available is 0.20 × 345 × 2,000 or 138,000 pounds. The trailing tons that could be handled over this grade on a short-time basis is:

$$\frac{138{,}000}{20+1+4} - 345 = 5{,}175 \text{ tons or } 104 \text{ 50-ton cars}$$

The time on the grade at the short-time rating would be:

$$\text{Time (minutes)} = \frac{\text{Distance (miles)}}{\text{Speed (miles per hour)}} \times 60$$

$$= \frac{1.19}{9.5} \times 60$$

$$= 7.5 \text{ minutes}$$

Referring to Figure 2, it is seen that the speed over the grade at the short-time tractive effort rating is 9.5 miles per hour.

The capacity of a Diesel-electric locomotive is expressed in two ways, the continuous rating, and the short-time rating. The short-time rating is actually a $1^1/_2$-hour rating based on the temperature rise of the motor windings. Where the grades require over 90 minutes to ascend with a given train, the continuous rating must be used, otherwise the temperature rise will be excessive with consequent damage to the motor windings and insulation.

Speed and Acceleration

The correct size of Diesel-electric locomotive should be selected, furthermore from a preliminary investigation of the speed desired over the ruling grade with a given weight of train. Then a locomotive tractive effort–speed curve is made up which is used in calculating the speed of the desired train. In the usual manner, the grade, curve and train resistances are algebraically added to the tractive-effort values found from this curve, to obtain the net amount of tractive effort for acceleration of the train.

Since the grade, curve, and train resistance are expressed in pounds per ton, the locomotive tractive effort–speed curve is plotted on the same basis. The grade resistance is taken at 20 pounds per ton for each per cent of grade. The curve resistance is calculated at 0.8 pound per ton per degree of curvature. The train resistance is determined from the formulas developed by W. J. Davis.[1] These formulas are used to express the total resistance tending to reduce the locomotive

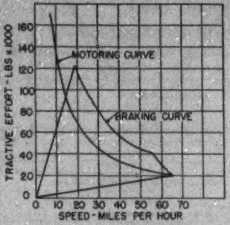

Figure 2. 4,500-horsepower Diesel-electric locomotive tractive effort and braking curves

speed, which consists of journal, flange, and air friction. The force required to accelerate one ton at one mile per hour per second is, for straight line acceleration, 91.1 pounds. This is derived from the well-known formula:

$$F=MA \qquad F=\frac{W}{32.2}\times 2{,}000\times A\times\frac{5{,}280}{3{,}600}$$

$$=\frac{W}{g}A \qquad =91.1WA$$

where

F = accelerating force in pounds
W = weight in tons
A = acceleration in miles per hour per second
M = mass
g = gravity constant

When the rotational inertia is taken into account, at approximately 10 per cent of the linear inertia, the total net force required to accelerate a ton of train weight at a rate of one mile per hour per second will be 100 pounds. Therefore if the net tractive effort available for accelerating a 1,000-ton train is 25,000 pounds, the acceleration will be

$$\frac{25{,}000}{1{,}000\times 100}=0.25 \text{ mile per hour per second.}$$

The ability of a loaded train to make a rapid acceleration depends upon a number of conditions, the most important of which is the coefficient of adhesion between the locomotive wheels and the rails. Numerous tests have proved that, on a clean dry rail, an adhesion factor of 30 per cent is the maximum that can be attained without excessive slipping of the driving wheels. Rails that are wet or that have poor running surfaces, such as driver burns and so on, will materially reduce these values.

In the normal application of Diesel-electric locomotives, rates of acceleration of 0.3 mile per hour per second for freight service and 0.75 mile per hour per second for passenger service have been proved practical by experience. Variations from these rates depend upon the characteristic and type of train being accelerated.

Horsepower and Fuel Consumption

By taking increments of the speed in accelerating a specified train, the time in seconds can readily be obtained. From this, the increment distance can be calculated. Thus, increment horsepower is obtained from the formula

$$HP=\frac{TE\times MPH}{375}$$

where

HP = horsepower
TE = tractive effort in pounds
MPH = speed in miles per hour

When the increment values of horsepower and time are known, the horsepower hours can be quite easily calculated. The total fuel consumption for a given operation can be obtained if the Diesel-engine fuel rate is known. Thus the speed–distance–time calculations and plotting of the data will give a complete history of the train movement.

Railroad operation requires four distinct locomotive services:

1. Yard-switching service includes switching work in passenger and freight terminals, classification yards, and local way-freight service.
2. Transfer service includes the movement of trains from one point to another, generally within a terminal territory.
3. Branch-line service includes freight and passenger operation on secondary lines of light traffic density.
4. Main-line service includes freight and passenger service in through main-line terminal-to-terminal operation.

Switching Service

The most striking replacement of steam locomotives has been in yard-switching service, principally because the Diesel-electric locomotive offers the following advantages:

1. Full utilization of Diesel-engine horsepower output.
2. Saving of time through higher acceleration rates.
3. Fuel savings up to as much as 50 per cent over steam.
4. Greater locomotive utilization.

A comparison of the tractive effort–speed curves for typical Diesel-electric and steam locomotives is shown in Figure 3. It is quite obvious that the full horsepower output of the Diesel-electric in the low-speed range gives this type of power supreme advantage in yard operation.

In the application of Diesel-electric locomotives to yard service, a knowledge of the particular operating conditions is necessary. The frequency of

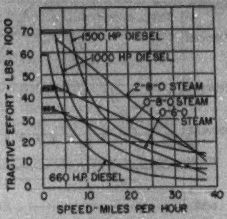

Figure 3. Comparison of tractive effort and speed characteristics of steam and Diesel-electric switching locomotives

yard movements, as well as the maximum number and tonnage of cars handled, must be determined first. As a general rule, a 660-horsepower Diesel-electric will replace a 6-wheel steam switcher; a 1,000-horsepower Diesel-electric will replace an 8-wheel steam switcher, and a 1,500-horsepower Diesel-electric will replace a Consolidation or a Mikado steam locomotive when used in yard service. The average yard operation is carried on at a speed of 6 to 8 miles per hour; consequently, speed–distance curves are of little value, since the distance a given train moves is comparatively small.

Transfer Service

In transfer, branch-line, and road service, however, the speed–distance curve is quite helpful in analyzing the scheduling of trains, and also in determing fuel consumption. Here again, a knowledge of the particular operations involved is necessary in order to establish the correct size of train. For instance, the line and profile may show that a 6,000-horsepower locomotive could handle a 125-car freight train.

Proper knowledge of the traffic conditions, the frequency of trains, or the length of passing sidings on single-track lines is also necessary to determine whether such a large-size locomotive can be used. There have been cases on several single-track railroads in which full utilization of the complete flexibility of the Diesel-electric locomotive could not be realized simply because the passing-track capacity limited the size of the train to be handled.

Furthermore, the Diesel-electric locomotive offers complete flexibility of motive power for around-the-clock operation. For example, in branch-line service a Diesel-electric road switcher of either the 1,000-horsepower or 1,500-horsepower size can perform passenger service in one direction on a run, and mixed-train or

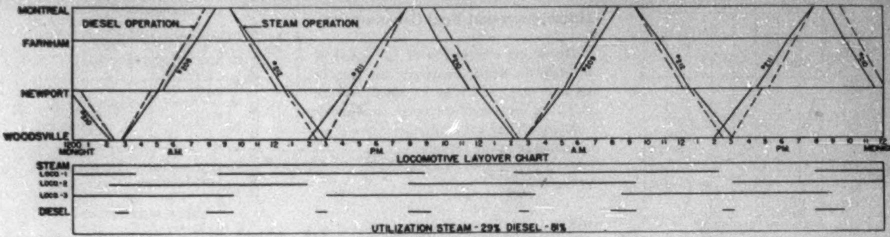

Figure 4. Graphic train sheet, steam versus Diesel-electric operation

way-freight service in the opposite direction, with equal efficiency. In this case, the scheduling of trains is such that one locomotive may make a complete round trip, whereas with steam-operation characteristics, passenger-train service may require a type of locomotive unsuited for the handling of a freight train on the return trip.

The flexibility of the Diesel-electric has been demonstrated further by the fact that this type of road-switcher locomotive has been used in triple-service around-the-clock operation on a railroad handling commuter traffic. During the rush hours, they handle commuter passenger trains. Then, during the daylight hours of industrial activity, these same locomotives are used in straight switching service. Finally, during the night hours, they haul freight trains on transfer runs, either singly or in multiple-unit operation.

Road Service

The Diesel-electric locomotive is ideally suited to this universal type of operation inasmuch as the Diesel engine develops constant horsepower over the entire locomotive speed range. The electric transmission in turn translates this horsepower into either high tractive effort at low speed or low tractive effort at high speed. This characteristic, by and large, makes a more dependable locomotive, both from the standpoint of schedules and of handling full tonnage under all kinds of climatic conditions. It is common practice with Diesel-electric locomotive operation to disregard the freight-train tonnage reduction formerly made in severe cold weather. The short-time overload capacity of the Diesel-electric enables it to start the same train in zero weather as in summer. In many instances with steam operation, the same train would require helper locomotives in cold weather.

In one instance, the supremacy of Diesel-electric was demonstrated by the complete elimination of steam-locomotive helper service over a ruling grade of 2.17 per cent for 1.5 miles. By taking advantage of the short-time overload capacity, the Diesel-electric was able to handle the full tonnage over this short, heavy grade without the use of helper locomotives.

The graphic train sheet, such as shown in Figure 4, has been used to considerable advantage in determining the number of locomotive units required to perform a given service. The Diesel-electric does not have to return to the engine house after every trip for cleaning of fires and replenishing of the water and fuel supply. Consequently, it can double back on a return trip within a few minutes after its arrival at a terminal. By analyzing the train movements graphically, therefore, maximum utilization of the Diesel-electric can be secured. In the case illustrated, one Diesel-electric can replace three steam locomotives.

One salient feature of the Diesel-electric locomotive that is of great value in mountainous territory is the dynamic brake, which uses the traction motors, acting as generators, to retard the train when descending heavy grades. On long, heavy, down-grade movements with steam operation, the air-brake retainer valves on the individual cars must be set before going down grade. This necessitates a stop at the top of the grade. If the grade is long and severe, two or three intermediate stops will be required to cool the brake shoes and wheels. One western railroad has indicated that, prior to the use of Diesel-electric locomotives, 2,500 wheels per month were removed on account of brake burns. Likewise, a considerable saving is realized by the elimination of the wear and replacement of brake shoes. The dynamic brake is much more reliable and results in safer operation, since the wheels and brake shoes do not become overheated.

As a general rule, Diesel-electric locomotives with dynamic braking can satisfactorily handle the same tonnage train either up or down grade. As a typical example, reference to the dynamic-braking curve in Figure 2 indicates that a 1,650 trailing-ton train can be handled down a 3 per cent grade with 6-degree curves, assuming 4.2 pounds per ton train friction. The total train resistance is the algebraic sum of the grade, curve, and train friction, or:

$-60+4.8+4.2=-51$ pounds per ton

(Train weight + Locomotive weight) × Total resistance = Braking effort

$1{,}650+345\times 51=101{,}745$ pounds

The braking curve, at 101,745 pounds braking effort, shows a speed of 5.5 miles per hour.

In handling the same train up the grade, the tractive effort required will be:

$$(1{,}650+345)\times 69=137{,}500 \text{ pounds}$$

When exerting a tractive effort of 137,500 pounds, the locomotive speed will be 9.5 miles per hour as shown in Figure 2.

Analysis of Operating Expense

With a working knowledge of the train schedules and projected use of Diesel-electrics in the place of steam locomotives, the economics of the application can be determined, provided that additional data are available relative to the cost of operation. This information requires a complete breakdown of those operating expenses that are affected by motive-power operation. Railroad accounting classifies these expenses in eight different items as shown in the following tables. The largest saving of the Diesel-electric compared to the steam is in fuel expense. The reason for this is that the Diesel-electric has a thermal efficiency at the wheels of 25 per cent, whereas the corresponding figure for a modern steam locomotive is only 5 per cent.

Figure 5 shows the comparison between the costs of Diesel fuel oil and coal. The recent increases in fuel-oil cost have been paralleled by a corresponding increase in coal cost, so that the advantage of using fuel oil remains the same under the present price level. The savings in fuel cost with Diesel-electric operation may run as high as 60 per cent, depending, of course, on the relative prices of coal and oil.

Should the price of Diesel fuel oil advance to 20 cents per gallon, the cost of coal per ton for use in steam freight service would have to be $5.20 in order to match the fuel-oil cost. Any price higher than $5.20 would favor the Diesel-fuel cost and result in a saving over steam operation.

The second item reflecting a saving is the locomotive repair account. Steam locomotive repair cost is, on the average, approximately 10 per cent to 40 per cent higher than that of the Diesel-electric, depending upon the age of the steam motive power. The necessity of removing flues every four years, as well as costly firebox repairs, accounts for the increased maintenance on steam locomotives.

Engine house expense is the next item of comparison in which the Diesel-electric shows direct savings over steam operation. This expense covers the routine work at a terminal required to prepare a locomotive for its next run, including the cost of wiping and cleaning the locomotives,

cleaning fires, dumping ashes, fire watching, and removing ashes.

The remaining items chargeable to locomotive operation include enginemen's and trainmen's wages, water, lubrication, and other supplies. With the exception of water account, which is considered negligible, these costs are approximately the same for Diesel operation, since the amount used for Diesel engine cooling and train heating is insignificant compared with that consumed in steam-locomotive operation.

A typical comparison of these eight items for steam and Diesel-electric operation for switching service is shown in Table I.

Since the daily mileage operated over by switching locomotives is rather low, and since considerable idling time has to be accounted for, it is necessary to use the hours operated per day as a means of comparison. Hence these switching-unit costs are based on locomotive hours.

In road work, on the other hand, the locomotive miles per day, month, or year give an indication of how much service a locomotive accumulates. Unit costs, therefore, are compared on the basis of train miles or locomotive miles. In the case of operating costs, a more correct comparison is obtained on the basis of the amount of work performed, which is represented in passenger service by car miles, and in freight service by thousands of gross-ton miles.

A comparison of the operating costs on a branch line of an eastern railroad where the steam locomotives are approximately 30 years old is shown in Table II.

A typical comparison of operating costs for a completely Dieselized, major Class-I railroad is shown in Table III. Here again, the operating savings in the fuel, locomotive repair, and engine house accounts are clearly evident. This program involves the replacement of 188 steam locomotives with 126 Diesel-electric locomotives. This replacement seems justified from an economic standpoint by the fact that a return of 24.2 per cent on the gross investment is possible. The reduction in operating expense accomplished by dieselization amounts to 42.5 per cent.

Conclusions

A locomotive, regardless of type, is more than a thermal and mechanical unit designed to develop ton-miles per hour. The first cost and efficiency of performance are the basic factors determining its selection. Efficiency of performance means not only availability, reliability, flexibility, and tractive-effort characteristics; but also includes costs of maintenance and operation.

From an initial investment standpoint, the first cost of steam motive power has advanced considerably in recent years, mainly due to the purchase of custom-built designs, and also to the smaller number of equipment manufactured. By comparison, the Diesel-electric has had a downward price trend largely due to standardization and quantity manufacturing practices. Consequently, on a dollar-per-horsepower basis, the operating savings with Diesel-electric motive power appear very attractive. The Diesel-electric locomotive, by its ability to operate on a round-the-clock performance, to operate in locations where water is hard to treat, and to eliminate costly engine house and other terminal inspections necessary with steam locomotives, has revolutionized the railroad industry. This newer type of motive power also has reduced, in many cases, the need for helper-locomotive service over mountainous routes. For these reasons the application of Diesel-electric locomotives to the railroad field has proved to be economically justified.

Twenty-Five Years Progress in the Design of Traction Motors

M. J. BALDWIN
MEMBER AIEE

ALTHOUGH the traction motor at some 60 years of age is one of the oldest in the electrical industry, nevertheless it is a thriving oldster with an annual output of approximately 2,500,000 horsepower which has in the past quarter of a century staged a decided come-back due to the rapid development of the Diesel-electric locomotive.

This period has also been marked by the development of the PCC (President's Conference Car) standardized trolley car; the increasingly popular trolley coach; and by the application of 3,000-volt trolley power to commuter service multiple-unit cars and to new types of locomotives both here and abroad.

It is the purpose of this paper to review the progress that has been made in traction-motor design, and to note the particular design changes that have contributed to the improvements made.

Design Objectives

Traction motors are designed primarily for minimum weight. This is particularly true for trolley cars and coaches where weight is at a premium, and also, to a somewhat lesser degree, for rapid transit. For Diesel-electric locomotives where so much vertical space is required by the engine, a small wheel size is also important. On trolley locomotives, additional weight in the motors usually would be permissible, where ballast is used, to obtain required weight on the locomotive drivers. Large heavy motors have found, however, to add more to the cost of a locomotive than is saved in ballast.

Efficiency plays but a minor role in traction-motor design. Any increase in efficiency, if obtained at a cost of increased weight, tends in general to be offset by the added cost of hauling this extra weight around. Nevertheless there has been a decided gain in efficiency as speed and horsepower have increased.

Comparing Motors—Speed-Ratio Power

Two factors are of primary importance in measuring the application capacity of a traction motor: (1) continuous rated horsepower and (2) the ratio of maximum permissible to rated speed. The first factor, rated horsepower, requires no comment since this is accepted generally as the primary if not the only measuring unit. The traction motor, however, must be rated at a relatively low speed; and it must also be capable of operating at maximum permissible speeds ranging from two to five times its rated speed. If variation in rotation losses with speed could be ignored, and if the ratio of mechanical to electrical material could be assumed to be a constant, a motor with a speed ratio of five, would have five times the tractive effort and five times the size and weight of an equal horsepower purely hypothetical motor rating only at the maximum permissible speed. The product of these two factors: the ratio of maximum to rated speed, and the rated horsepower is here called "speed-ratio power" and is used to compare, in Figures 1 to 7 inclusive, the advances made over the years in the various lines of motors. Gains range from 70 to 300 per cent depending upon the application.

Speed-ratio power is an accurate measure if used to compare motors that are not too widely apart in peripheral speed at the rating. In each case, the comparisons here made are for a given class of service, and the error due to differences in peripheral speed is estimated to be not over five per cent.

Sources of Advancement

Advances in the design of a motor as old and established as the traction motor are arrived at generally in such small steps that it is not until the history over a relatively long period of time is reviewed, as has been done in the comparisons mentioned before, that the over-all progress can be appreciated. The advances have been brought about by an accumulation of quite a number of seemingly small changes.

Antifriction Armature Bearings

The first significant change that took place during the past 25 years was that from the waste-packed sleeve to the antifriction type of armature bearing. Compared to the sleeve type, any benefit that may have resulted from the reduction in friction due to the antifriction feature was incidental although there is no doubt some slight reduction in torque loss on an initial cold start. The antifriction bearing, however, does have three advantages over the sleeve: it operates at high speed with simple and reliable lubrication; it requires less axial space allowing room for increased active material; and the negligible wear with which it operates makes possible better maintenance of gear centers.

The principal problem in connection with the use of antifriction armature bearings has been to keep the lubricant in, and dirt and water out. The solution has been fairly well worked out for grease. Oil is an ideal lubricant for antifriction bearings and very little is required in the bearing at any time. Leakage and vaporization make it difficult to confine and means must be provided to continually

replace that which is lost. Where oil is the gear lubricant, it is possible to obtain an adequate supply for the pinion-end bearing from the gear case. In this instance, however, general practice is followed in that the commutator-end bearing is grease-lubricated.

Gearing

On large-size traction motors at the beginning of this 25-year period, twin gearing usually was used. Two gears, pinions, and gear cases were required, one pinion being mounted on each end of the armature shaft, and one gear being mounted on the locomotive axle or wheel hub at each end of the motor. Equalization of gear loading was obtained by the use of springs between the rim and the center of each gear, tangential motion being permitted between the two parts in these spring or cushion type gears. About 20 years ago, twin gearing of this type was replaced by single gearing using solid gear, pinion, and gear cover. This change gained added space axially for active material in the motor core and effected an appreciable cost reduction.

Elimination of the second set of gears was in part made possible as a result of the better gear center distance maintenance resulting from the use of antifriction armature bearings, as has been noted; but there also were improvements made in the fundamental design of the gears and pinions. The gearing of the older twin-geared motor was cut and heat treated, but left relatively soft to permit wear in service to equalize cutting variations in the teeth and the tooth spacing. With the development of equipment for grinding tooth profiles after heat treatment, a harder, stronger gear material was used. The pressure angle of the teeth was increased to obtain more strength in bending. The two small fillets and short tangential section connecting adjacent teeth were changed to a single long radius fillet to minimize stress concentration in the pinion hub and gear rim. The grinding of the profiles improved the division of load on the teeth and minimized the torsional stresses in the armature shaft caused, particularly at high speed, by variation in spacing of the teeth.

Another popular way of obtaining high gear reduction is by making the pinion integral with a short shaft supported by bearings adjacent to the pinion on both sides. This so-called "straddle-mounted" pinion can be made unusually small. Its use has been found practical where the gear unit is separate from the motor, as is the case for truck or body-mounted motors used on PCC cars, trolley coaches, and at least one of the most recent medium-sized traction motors.

Double-Reduction Motors

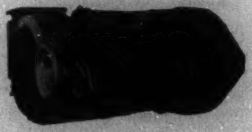
In the past ten years, the double-reduction traction motor has come into widespread use for internally-powered locomotives operated principally in switching service. Motors of the general type shown at the right in Figure 5 have two reductions; the high speed being of the spur type, and the low speed being a hypoid. All bearings in the case, the pinion-end armature bearing, and also the axle linings are lubricated from the same oil bath. Only the commutator-end bearing of the motor is separately lubricated with grease.

Commutators

Increases in armature speed have been made possible largely as a result of corresponding improvements in commutators. On all high-speed motors, particularly those used in road service, the commutators are spun. This is the word generally used to designate the curing process. It consists of an indeterminate number of cycles of heating while revolving at high speed, cooling and tightening, which are repeated until a commutator surface is obtained that is smooth and relatively unaffected by variations in either speed or temperature. This process is expensive, but at present appears necessary to obtain commutators which are good for the maximum operating speed of approximately 10,000 feet per minute currently used for most railway motors. Increasing use of commutator spinning has been made from about 1925, the details of the process being continually the subject of developmental work, seeking means of obtaining better commutators.

Instead of the usual V-bound commutator, a few of the most recent motors have been equipped with arch-bound commutators. In this type the retaining V-shaped sections of the cap and shell

Figure 3. Progress in specific motor output, internal-power road locomotives



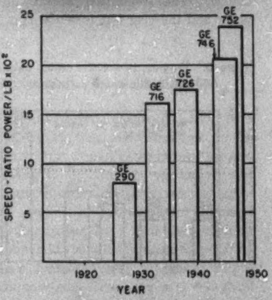


Figure 4. Progress in specific motor output, internal-power heavy switching locomotives

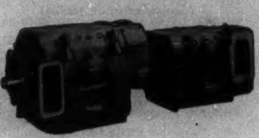
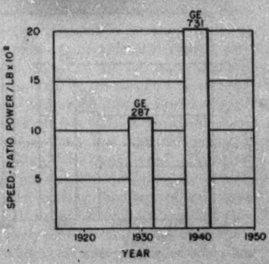




serve only as retractors to draw the bars in toward the center of the commutator and thereby build up tangential or arch pressure between the segments. In the so-called V-bound type, the bars are clamped axially between the V-shaped sections without developing high pressure between the bars. Of the two types, the arch-bound commutator generally has a somewhat better surface and requires less spinning.

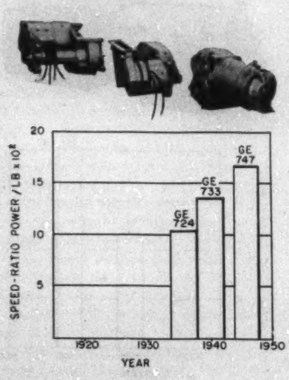
Brushes

Along with improvements made in commutators there have been complementary improvements made in brushes. Brushes having a porous surface have been developed that are sufficiently nonresilient to follow the minute variation in the surface of commutators. Extensive use has been made during the past eight years of the split-type brush consisting of two parts, each half the thickness of the usual solid brush. Both the change in material and this splitting have resulted in the brushes maintaining more intimate contact with the commutators, particularly at high speed, and have effected a marked improvement in commutation.

Binding and Wedging

The windings of most armatures today are held in the core slots by means of wedges, where formerly magnetic steel binding wire was used. When nonmagnetic steel wire was developed, it was used where needed as a means of reducing cross slot flux, thereby improving commutation; and also as a means of reducing band losses, thereby improving rating. With further increases in core speed and corresponding increases in the required amount of binding wire, it became necessary about 1930 to begin to use slot wedges in the core portion. This change eliminated banding loss in this region entirely and increased heat dissipation from the core teeth. Core speeds today are approaching 13,000 feet per minute at the maximum permissible vehicle speed in service.

Figure 5. Progress in specific motor output, internal-power light switching locomotives (double-reduction gearing)



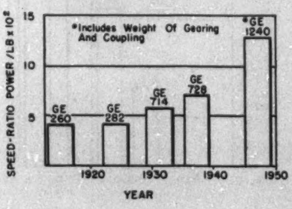
Reroll Banding

In order to bind the end windings down solidly, a relatively new practice termed "reroll banding" has been established on some of the higher speed motors. This operation consists of applying a layer of binding wire, anchoring it at both ends but running one strand over a pulley which is arranged to apply tension in this loop and to take up any slack. The wire is reeled over this pulley as the hot armature is rotated as shown in Figure 8 and the high-tension loop travels backward and forward across the winding surface distributing the pressure to all portions of the winding. In the core portion, a steel bar is temporarily laid along the coil in the top of each slot during the binding process. These bars are free to move radially and are of sufficient thickness so that the binding pressure is applied to them, and through them to the core portion of the winding. By means of the rest of the turns of wire, the pressure is retained until no additional slack can be taken by the traveling loop.

Truck-Mounted or Body-Mounted Motors

On most of the small railway motors, such as the ones used on PCC cars and trolley coaches, the axle-mounted motor has been abandoned in favor of a motor mounted on the truck frame or body of the vehicle. The connection between the motor and the gear box is of the double universal-joint type quite similar to the ones used on trucks and automobiles. Relatively high gear reductions are made possible in these automotive-type gear boxes. The corresponding increase in speed-ratio power per pound is indicated by comparing the older trolley-car motors with the PCC car motors in Figure 7.

Figure 6. Progress in specific motor output, 600-volt multiple-unit car motors



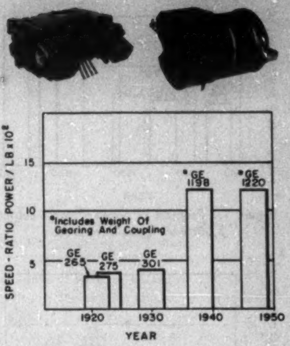


Figure 7. Progress in specific motor output, 600-volt street railway motors

Ventilation

Ventilation has been increased on most traction motors, particularly the larger sizes which today are blown somewhat harder than was considered economical a few years ago. Early traction motors were made to rely more upon thermal capacity than those designed today. Some 30 years ago motors were series ventilated, a practice which limited the amount of air to that which could be forced through the armature. Today practically all traction motors are multiple-ventilated, the air going through the machine in two parallel paths, one through the armature and the other through the air gap and between the stator coils. In the case of motors insulated for 600 volts or less, the air velocity has been increased in the last 10 years from about 3,000 feet per minute to its present approximate value of 5,000 feet per minute. On the higher voltage, thicker insulated motors it has not been found worthwhile to blow very hard due to the unaffected thermal resistance of this dielectric.

Insulation

The size of a given motor is affected to a marked degree by the thickness of the insulation. Thick insulation not only reduces the amount of available space for

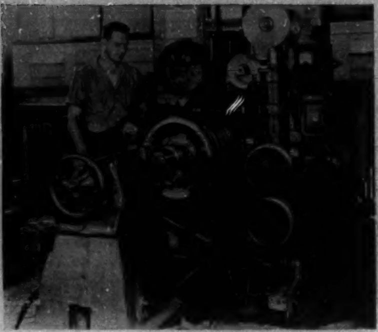

Figure 8 (left). Apparatus for re-roll binding of armatures

Figure 9 (right). Commutating field coil for motor used on internal-power locomotives

copper or steel, but also increases the resistance of the thermal path by which heat must escape from the copper. The problem is to obtain an insulation that is consistently good, that may be applied with normal shop handling without becoming damaged, and one that in service will stand class "B" temperatures or higher.

Class "A" materials are not being used on modern traction motors. Mica has been and still is the basic class "B" insulating material. Mica insulating tapes and sheets have been improved by the use of thinner retaining paper. This newly-developed material is but one-half mil in thickness—approximately half the former thickness—but has adequate strength. As this paper is permitted only as a means of applying the mica, the less used the more heat proof and more strictly class "B" is the insulation. Increasing use is being made of glass-baked mica tape which completely eliminates class "A" material from the insulation.

Glass outer protective insulation has largely supplanted asbestos. The glass has more per-unit tensile strength making possible a tighter taping or wrapping of coils, and also a saving in insulation space.

A change was introduced about eight years ago in the method of insulating commutating coils where fields may be connected in the circuit at approximately ground potential, and where the motor is for use on locomotives operating on internal power. The so-called "mummified" type of insulation in which the coil is completely taped together, has been abondoned as being unnecessarily large and heavy for this particular kind of service. Instead, the first two or three turns, depending upon creepage needed, are taped separately with ground insulation providing full thickness on the end turns and tapering the insulation to provide fewer tapings on the inner turns. Center turns are left bare. The commutating pole is wrapped with insulation, the coil assembled on the pole, the entire unit impregnated in synthetic varnish, clamped on blocks to simulate assembly in machine and cured in an oven into a practically incompressible, hard unit.

Coils of the type just described are used on small locomotives, where only one connection of motors is required. On larger locomotive motors where 2-motor combinations make necessary operation of field coils at more than ground potential, a similar coil is now being used mounted on a metal spool instead of directly on the pole. Here again this is done only for use on locomotives operating from internal power. Permafil, a new synthetic thermo-setting varnish, is used for mica insulation bonding and final impregnation. Center turns on these coils are individually glass taped. These coils are air-cured, clamped in a mold and heat-treated into an essentially incompressible, hard unit which, however, differs from the smaller coils in that the commutating pole is removable. The design is indicated in Figure 9. The coils are held in place on the pole by means of multiple-leaf, nonmagnetic spring pole tips.

Reduction in Use of Castings

The past quarter century has seen much of the work that was once done in the foundry transferred to the fabricating and welding shop. Only in the largest size magnet frames are castings more generally used than fabrication. Wherever possible frames have been changed from octagonal to round and formed by rolling at a reduction in cost. Where space limitations require a rectangular or octagonal shape of frame, the cost is marginal and the change to fabrication may or may not prove economical.

Fabrication of stators using punched sections welded together have been made on an experimental basis. Figure 10 shows how this type of frame appears after welding and before machining, and also the appearance of motor completed. These experimental machines have operated successfully in severest subway service for 15 years. This construction offers some advantages, particularly where electrical transients are severe.

While fabrication is used or not used largely on a cost basis, both the rolled plate and punched fabrication offer a more uniform flux-carrying medium than castings in which unseen blow holes and porosity are likely to occur.

Commutator shells and caps are now made generally from forgings instead of castings wherever the quantity involved is great enough that this construction proves most economical. Frameheads are being "hogged" more and more from ordinary welding plate instead of being made from castings.

Electrical Design

Although not so apparent, a number of changes in electrical design have been made during the past few years. Many of the more recent motors have made use of the twisted-lead type of armature winding, Figure 11, instead of the solid, deep bar; the stranded wire type, Figure 12; or the transposed bar types, Figures 13 and 14. The twist-lead type of armature coil offers high slot-space efficiency combined with low eddy-current loss, both effecting increases in armature capacity. The cost of the twist-lead type is also lower than that of the transposed-bar types. It is on the motors with three or more coils per slot that the twist-lead type of coil offers a gain in combined space efficiency and low loss as compared to coils of the other types. The more coils per slot, the more the gain on both counts, making this type of coil most useful in higher voltage motors, particularly for 3,000-volt trolley operation.

While resulting in a reduction in heating

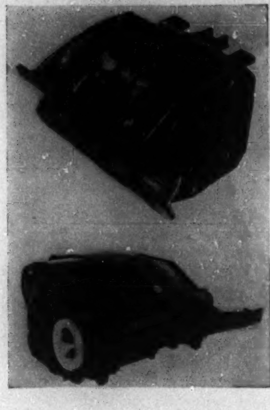

Figure 10. Motor with frame fabricated from punched shapes by welding

and increase in rating, the use of a shallow conductor increases the problem of obtaining a suitable adjustment of compensation to meet the requirements of all coils in a given slot. The eddy currents of the deep conductor tend to equalize the rate of change of current in the several coils during commutation, and also tend to cause some of the energy of commutation to appear in heat rather than sparking. The proper balancing of commutation difficulties against heat reduction is always a problem for any shallow conductor winding when it is used where commutation is inherently difficult.

Windings of the bar type have been used for many years in coils in which the back pitch is not a multiple of the coils per slot. Coils of this type are usually brazed at the end opposite the commutator, necessitating a removable flange and special molded flange insulation; all tending to make this type of coil expensive. There is, however, a definite gain in reduced commutator maintenance when this type of back pitching is used as compared to similar motors where the coil back pitch is a multiple of the coils per slot. In order to take advantage of the twist-lead coil and still use the special back pitching of the bar-type coil, many motors now use a modified form of this twist-lead type of coil which is ordinarily known as the "orphan coil." The design of this type of coil is indicated in Figure 15. Such windings have slot space efficiency comparable to the bar types and are somewhat less expensive in over-all armature cost.

About 1930, it was found advantageous

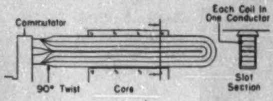

Figure 11. Twisted lead armature coil

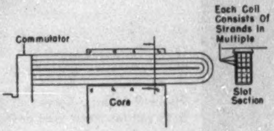

Figure 12. Conventional stranded conductor armature coil

to increase the amount of iron and decrease the amount of copper compared to the ratios used previously. The optimum proportion insofar as the armature is concerned has been found to be about two parts of iron to one part of copper in the effective circumference of the armature. This proportion works out well on motors having more than four poles. On 4-pole motors, it has generally been found advantageous to use a little higher percentage of copper to avoid excessive flux density in the armature core beneath the teeth.

In order to reduce peak voltage between adjacent commutator bars caused by flux distortion, it has been found desirable to increase the air gap from a minimum value at the main pole center to a maximum at the tips. Gaps flared in this way, in addition to reducing flux distortion, also tend to limit losses in the tips due to pulsation in flux caused by the passing of the armature teeth.

Standardization

In the last 20 years, much progress has been made in all lines of traction motors toward the adoption of standard machines. The adoption of a standard trolley-car motor as a result of co-operative developmental effort on the part of the car operators put this type of vehicle in competition with the gasoline coach. Similar co-operation between the operators and the manufacturers has resulted in the idea of a standard motor being carried over into the trolley bus application.

In the field of trolley locomotives, the manufacturers are attempting as much standardization of motors as the several gauges of track and variations in trolley voltage will permit. Designs in this field, however, are still largely determined by the customer through limiting specifications, although every effort is being made

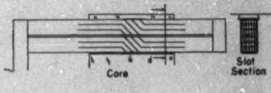

Figure 14. Folded bar armature winding

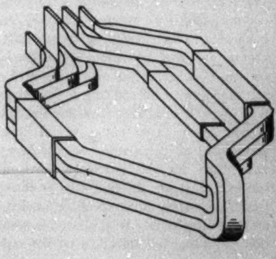
by the manufacturers in this country to adopt standards. Where complete motors are not standard, certain parts are being used as far as possible on different applications.

The internal-power locomotive offers the best possible opportunity for standardization on a widely-applicable motor for several different weights of locomotive. The motor shown at the right in Figure 5 is used on 25-, 45-, 50-, 65-, and 80-ton locomotives. Different numbers of motors per locomotive and different gear reductions are used depending on the maximum speed desired, which ranges from 25 to 50 miles per hour. This motor is made to be applicable on any track gauge down to 36-inch minimum.

For road locomotives of 50,000 pounds per axle or over, each manufacturer appears to have adopted a standard motor. Generators are designed to fit the motor since there is less than half the cost in the generator that there is in the motors of a 4-motor locomotive. Not only is there a greater percentage of the equipment cost in motors than in generators, but there is also a larger number of smaller units. Both of these considerations favor motor rather than generator standardization.

It is of interest to note that the motor for internally-powered locomotives is being reduced in size to a point where wheel diameter, instead of being deter-

Figure 15. Orphan-type armature coil



mined by motor size, is now in some cases on the heavier road locomotives being determined by the weight on the driver—that is by the per-square-inch pressure on the rail.

This situation is new and is welcomed as a possible aid to motor standardization. If the wheel rather than the motor does become limiting, a greater freedom is allowed in the choice of gearing for a small motor or, conversely, the way is opened for a more universal motor not requiring specialized gearing.

Standardization tends to reduce first cost and makes faster servicing possible, particularly where the volume is sufficient to make unit exchange possible.

Maintenance and Unit Exchange

The railway motor of today, like the automobile, is more complex, much more of a precision tool, and inherently more difficult to maintain than was the slower speed motor of 20 or 30 years ago. As in the automobile service shop, the problem of keeping the traction motor service shop fully informed regarding improved factory methods is one that is being solved by specialized training of service personnel supplemented by factory instruction sheets. The improved processes for binding, balancing, and spinning armatures and improved equipment for handling and testing is being used in the service shop as well as the factory in order to insure uniformly good operation from new and rebuilt equipment.

Little of the increased maintenance problem is apparent to the operating railroad which uses standardized motors where unit exchange is available. Under the unit-exchange system, the operator turns in a motor needing service and receives, with essentially no delay, a rebuilt motor in exchange. This method of handling service is one of the most important results of standardization which is not possible with custom-built apparatus. The system of unit exchange spreads the cost of specialized servicing equipment over many users of a given motor.

Conclusion

The principal way in which power per pound has been increased during the past 25 years has been by means of increases in speed. Considering the limitations imposed by available known materials—fundamentally copper, steel, and mica—this increasing of speed has proved to be the only way to accomplish progress in traction-motor design. Much work is being done currently in developing new synthetic insulating materials which may one day clear the way to increased specific output. Higher than class "B" temperatures are also being advocated for railway work. Further speed increases are to be expected despite increasing mechanical problems involved. The curves of output per pound are continually increasing. The interesting problem presented to the engineer is to see that they continue to do so.

The Renaissance of Electric Motive Power

A. H. CANDEE
NONMEMBER AIEE

THE DESIGN characteristics of the electric propulsion equipment of electric locomotives were thought to be well established by the development and use throughout the last half century of the trolley-electric or third-rail-electric locomotives which receive power from an external source. The widespread application of self-propelled electric locomotives and railcars over the past 23 years, however, and particularly the increased use of Diesel-electric locomotives (which have, within the past 12 years, threatened the existence of self-propelled steam locomotives) has developed new concepts of the design, arrangement, capacity, limitations, and advantages of electric propulsion apparatus for railroad motive power.

Any locomotive, whose propulsion is effected by means of electric motors mounted on it, is an electric locomotive, whether the propulsion power is generated elsewhere and transmitted to the vehicle, or whether it is generated on the locomotive itself. This term, then, is generic and embraces the trolley- or third-rail-electric, the gasoline-electric, the Diesel-electric, the steam-turbine-electric, the gas-turbine electric, and the storage-battery-electric locomotive. During the early stages of development, several builders of Diesel-electric locomotives purposely deleted the term "electric," claiming that the electric equipment was merely a transmission system and of secondary importance to the diesel engine, being a convenient but not entirely necessary accessory. Subsequent experience, however, has shown that many of the desirable operating characteristics of this type of motive power are directly attributable to the electric propulsion system, and that these same features are inherent in the steam-turbine-electric locomotive, the gas-turbine-electric locomotive, or any other self-propelled vehicle having electric drive. As a matter of fact, Diesel-engine-driven motive power would be highly impractical for general railroad use if it were not for the electric transmission and propulsion equipment, since there is no other torque-converting means with the wide range of application of the electric drive.

Tractive Force Improved by Electric Drive

Many railroad men have been astonished by the ability of a relatively low-powered Diesel-electric locomotive to outperform a high-powered (peak) reciprocating steam locomotive. This may be attributed, in part, to the tractive force characteristics of the electric system of power transmission and propulsion used with Diesel-electric motive power, which are available for any type of self-propelled motive power if electric drive is used.

In any properly designed electric drive, three characteristics are outstanding:

1. High tractive force for starting a train.
2. High available power at low train speeds.
3. The development of smooth, nonpulsating tractive force.

These factors, as compared to mechanical drives, permit easier and more positive starting of heavy trains, saving in time because of better acceleration, improved speeds on heavy grades, and fewer delays caused by wheels slipping.

The complication involved in driving the wheels of a self-propelled locomotive by mechanical means from a prime mover normally limits the number of wheels (or axles) that may be driven. Very few modern steam locomotives have more than four pairs of wheels (four axles) driven by a single prime mover, because such axles must be contained by a rigid frame and more axles make the rigid wheelbase too long for sharp track curvatures. In order to get high starting tractive force, then, the weight on this small number of driving axles must be high (if normal values of adhesion are considered), which is often impractical. This limitation is not present with electric drives, because traction motors may be applied to as many driving axles as may be found expedient. From this, it is clear that an electrically propelled locomotive may have vastly improved starting characteristics over any type of mechanical drive, and still stay within reasonable weights per axle and adhesive factors.

The power developed by a prime mover is a function of its speed. In any mechanical drive system, the speed of the prime mover and of the vehicle are related directly, so that full power is developed only at that vehicle speed corresponding to the full prime-mover speed. With a fixed relation between them, it is obvious that over the lower ranges of vehicle speed, only partial power can be obtained. In this respect, a self-propelled vehicle with an electric drive has a definite advantage. Since there is no mechanical connection between the prime mover and the drive wheels, the prime mover may be operated at its full speed and power at any locomotive speed. During acceleration of a train, or when negotiating severe grades, this feature is of considerable value in improving scheduled train speeds. Figure 1 illustrates the comparative speed—tractive-force—horsepower characteristics of a conventional steam locomotive and those of a self-propelled electric locomotive.

One characteristic of an electric traction motor is that its torque (tractive force) is

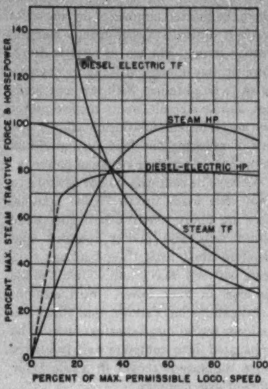

Figure 1. Comparison of locomotive characteristics

Reciprocating steam—4,250 horsepower at driver rims 4,000 horsepower Diesel-electric—3,350 horsepower at driver rims

of a continuous nature, without periodic variations or pulsation. In contrast, the tractive force of a reciprocating steam locomotive, especially at low speeds, is extremely variable (Figure 2). With such a locomotive designed for an average tractive force corresponding to a 25-per cent adhesive factor, the peak tractive force, which occurs once each wheel revolution, corresponds to an adhesive factor in excess of 30 per cent when starting a train. Since it is this peak force which determines the slipping point of the wheels, it follows that if a reciprocating steam locomotive does not slip at an average of 25-per cent adhesion (peak above 30 per cent), a locomotive with an electric drive will not slip at a tractive force corresponding to 30-per cent adhesion, and because of the continuous character of the force, this value may be maintained. By virtue of this, heavier trains may be started and handled much more easily than with a mechanical drive.

The preceding discussion has been based upon direct or geared drive by the traction motors. It should be recognized that when a traction motor or a prime mover drives wheels through a set of side rods, there may be an oscillation in the distribution of tractive force between the various pairs of wheels because of the reversal of side rod forces and clearances at the pins. These unequal tractive force values for the various wheels, then, may reduce the high effective adhesive values which are a normal characteristic of a direct or geared type of electric drive. It is considered inexpedient to apply electric drive through side rods if it can be avoided. It is preferable that direct gear drive be used wherever possible.

Most railroad motive-power men base their estimate of the worth of a locomotive on its tractive force characteristics rather than on its power. This is because, with a reasonable power output obtainable, high tractive forces for train starting and acceleration are of more importance than high power which can be developed only when operating at high train speed. This is one reason why the Diesel-electric locomotive, with its electric drive, has found favor among the operators of this type of power.

Independence of Prime Mover

Any prime mover, applied to a locomotive and transmitting its power to the driving wheels through a mechanical drive system, is subject to severe stresses and mechanical shocks, and definitely is limited in its application. The engines of a reciprocating steam locomotive have to be especially rugged because of this, but the simplicity of the connecting-rod and side-rod drive makes it desirable to accept this handicap. However, the connecting-rod and side-rod drive is limited in its application, since all drive wheels must be in a rigid frame for side-rod connection. As stated previously, this limits the number of axles which may be driven by a single pair of cylinders.

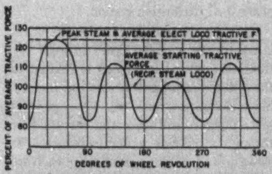

Figure 2. Tractive-force variation per wheel revolution, reciprocating steam locomotive

Electric locomotive can maintain 24 per cent higher tractive force than steam without exceeding steam locomotive adhesive limits

The application of an internal combustion engine with mechanical drive for locomotive propulsion is complicated somewhat because the engine must be kept running at all times even though the locomotive is stopped. This necessitates a clutch for disengaging the engine crankshaft from the drive mechanism. Also, since this type of engine is a relatively constant-torque machine, provision must be made for multiplication of the engine torque in inverse proportion to the locomotive speed. When such complication is added to that of driving a multiple number of wheels (or axles), the mechanical difficulties and the high maintenance expense make this type of drive impractical except for small locomotives and light duty. Furthermore, harmful road shocks are transmitted mechanically from the wheels to the engine. During accelerations with the engine at low speed, it is necessary to employ full engine torque, which is contrary to accepted practice for long service life of any internal combustion engine.

The use of an electric system of power transmission has contributed greatly to the success of the internal combustion engine (particularly the Diesel engine) as a prime mover for locomotives and railcars. Since the engine drives a generator for the conversion of its power into electric energy and is, therefore, independent of any mechanical relation to the driving wheels, this engine with its generator may be mounted in the most suitable location for accessibility and for weight distribution. Placing the power plant in a position where it readily may be inspected and repaired is conducive to its ready maintenance as an effective source of power, with a minimum risk of failure in service.

It is the present practice to design the automatic loading characteristics of an electric transmission system so that full torque will not be demanded of the prime mover until it approaches its full-load speed. This materially reduces engine stresses as compared with mechanical drives, and promotes long life as well as a reduction in repair expense. This electrical feature is considered to be one of the contributing factors to the success of the Diesel-powered electric locomotive.

The Hydraulic Drive

The transmission of power from the prime mover of a self-propelled vehicle to its driving wheels has been confined almost entirely to the mechanical or the electric system. Furthermore, the type of mechanical system which predominates is the side-rod drive of the conventional reciprocating steam locomotive, and the electric system has experienced its greatest application in connection with the Diesel engine. This raises the question as to why the hydraulic or fluid-drive transmissions have not been used more widely.

One of the most desirable characteristics of a power transmission system is the ability to drive any number of axles without mechanical complication, with whatever wheel arrangement may be found most desirable for the support of the locomotive structure and for good tracking characteristics. This requirement favors the use of individual drive of each axle. While the hydraulic drive—a fluid pump and one or more fluid motors—fulfills this basic requirement, the conduction of a large volume of fluid under extremely high pressure from the power pump to a multiple number of hydraulic motors mounted on and driving these individual axles, becomes a major problem—in fact, has been found entirely impractical. On the other hand, the fluid torque converter is not adaptable for individual axle drive, and has most of the disadvantages and complications of any mechanical system of power transmission.

Future of Electric Transmission Systems

Railroad motive power is undergoing a metamorphosis. For nearly 100 years the accepted type of power unit was the reciprocating steam locomotive. Then, the gasoline-engined railcar entered the field, inevitably followed by the Diesel-electric railcar and locomotive, which are rapidly replacing reciprocating steam power. Other locomotives have been built, or are under consideration, including steam-turbine units operating at conventional locomotive boiler pressures and with mechanical or electric drive, a steam-turbine-electric locomotive obtaining its steam from a new high pressure boiler, and the gas-turbine-electric locomotive. Because the advantages of electric drive are now recognized, it is predicted that few locomotives of the future, other than the reciprocating steam type, will be built with any drive other than electric.

Basic Type of Electric Transmission Equipment

The primary requirement of an electric power transmission system, as used for railroad locomotives and railcars, is the ability to convert the power available for propulsion into any desired speed-tractive-force combination necessary for the locomotion of the vehicle. Since horsepower is the product of the pounds of tractive force and speed (miles per hour) divided by 375, it follows that in any type of locomotive with a fixed maximum, prime-mover horsepower capacity, the speed of a locomotive changes in inverse relation to the tractive force requirement. Thus, the negotiation of a severe grade is always at relatively low speed, and high speeds are attained only when the resistance to train movement is reduced. Since the varying character of a railroad profile requires continual changes in the speed-tractive-force values, it is obvious that any electric drive system should permit an infinite variation in such relationship throughout the locomotive operating range, from the maximum tractive force required for train starting and acceleration to the maximum permissible locomotive speed.

D-c electric machinery is naturally adaptable to the variable requirements of self-propelled locomotives. By the use of a d-c generator (having means for varying its field strength) and series-type traction motors, variable values of speed and tractive force may be obtained in a very simple manner. As against this, nearly all of the simple and efficient a-c motors obtain their major speed variations through a change in pole combinations or in frequency of electric alternations. Since the generated frequency is a function of the prime mover speed, and since it is necessary to operate the prime mover at constant speed for obtaining its full power, any a-c system of locomotive power transmission becomes very complicated if variable frequency (and thus locomotive speed) is obtained. In the case of the electric locomotive receiving its power through a trolley wire from a single-phase a-c power supply, the disadvantage of a commutator-type a-c traction motor (which is a variable speed a-c motor) is accepted for the advantages of the a-c distribution system.

In a d-c system, tractive force is related to the current flow through the traction motors, and speed is related to the voltage impressed across the motors. Since electric power is a product of volts and amperes, and since the current flow through a traction motor increases as it slows down (such as caused by an increase in track grade) and vice-versa, it is only necessary to adjust the voltage of the generator in inverse relationship to the current flow in order to maintain constant power demand from the prime mover. The simplicity of this equipment and its regulation has resulted in a vast expansion in the use of d-c apparatus and has insured continued use of this system for railroad self-propelled electric vehicles.

Number of Traction Motors Per Locomotive

As has been mentioned, high axle loading has been the customary practice in reciprocating steam-locomotive design, where the limited number of driving axles makes it difficult to obtain high starting tractive force. The use of electric drive, however, has allowed still higher tractive forces to be obtained with low axle loadings, and as a result, many motive-power men are giving careful consideration to the idea of reducing the load on individual pairs of wheels with any type of power.

While some railroads do not hesitate to apply axle loads up to 70,000 pounds, there are many, many others that have lighter rails and poorer roadbed and therefore must limit their loadings to a figure between 50,000 and 55,000 pounds per axle, or even lower. Furthermore, investigations have shown that there is a tendency for rail-head shatter cracks to be propagated into complete rail fractures above the speeds shown in Table I for different axle loadings.

Table I. Rail Head Shatter Cracks Propagated into Complete Rail Fissures

Worn Wheel* Diameter, Inches	Axle Load, Pounds	Approximate Speed Limit, Miles Per Hour
36	50,000	90
36	55,000	72
36	60,000	56
36	65,000	42
38	50,000	105
38	55,000	85
38	60,000	67
38	65,000	52
40	50,000	120
40	55,000	98
40	60,000	78
40	65,000	62

*These wheel diameters are within the sizes used for self-propelled electric locomotives.

This further illustrates the desirability of low axle loadings in the interest of reduced rail failures. It is, of course, not always possible to keep to these low limits, but the figures serve as a goal toward which to strive.

It is apparent that low weight per driving axle may necessitate a large number of driven axles if high, starting tractice-force values are to be utilized at reasonable coefficients of adhesion between the wheels and the rail. It has been found that the practical starting tractive force values for the various types of railroad service are: switching service–50 to 65 pounds; passenger service–20 to 25 pounds; and freight service–35 to 45 pounds starting force per prime-mover horsepower. The preferred number of driven axles, then, may be calculated from these factors:

$$\text{Number of axles} = \frac{\text{Starting pounds per horsepower} \times \text{Prime mover horsepower}}{\text{Allowable pounds per axle} \times \text{Selected adhesive factor at start}}$$

Thus, for freight service, eight motored axles are desirable for a 3,000-horsepower Diesel-electric locomotive with a 55,000-pound axle loading and an allowable adhesive factor of 25 per cent, as follows:

$$\text{Number of axles} = \frac{35 \times 3{,}000}{55{,}000 \times 0.25} = 7.65 \text{ or } 8$$

Because of the electrical groupings of traction motors fed from a single generator, it is expedient at present to select the number of motors as a multiple of four or six. Diesel-electric locomotives are now available with 4, 6, 8, 12, 16, or 18 traction motors. In small sizes, one or two traction motors are sometimes sufficient.

Electrical Ratings

The use of an electric transmission system introduces a time factor into the application and use of self-propelled motive power which is not readily understood by the operating forces of a railroad who have been used to steam power with mechanical drive. This time factor is occasioned by the electric heating of the generators and traction motors.

Electric rotating-apparatus rating is based upon the current which can be carried continuously at a specified voltage without exceeding the safe temperatures established for its type of construction. This continuous current value is normally converted into a continuous tractive-force rating, and operation at a tractive force in excess of the rating will, if continued, cause the electric equipment temperature to exceed the established safe limit. However, if this overload tractive force is applied with the electric motors and generators at reduced temperatures, time elapses before the equipment reaches its maximum allowable temperature. It is these permissible overload ratings based upon time limits which confuse the average operating man.

The time factor is not a fundamental limitation of electric motive power, but is the result of commercial expediency. It is obvious that if large enough electric motors and generators were applied to give a continuous tractive-force rating exceeding the maximum that could ever be exerted (say, equivalent to 40-per cent adhesion between the wheels and rails), then no operating condition could ever arise which would overheat the equipment. This would require extremely large, heavy, and expensive electric machinery. In this age of modern self-propelled electric locomotives, competition makes it necessary to use motors and generators smaller than the ideal size in the interest of reduced equipment cost, and by so doing forces limitations in tonnage hauling capacity.

In reducing the capacity of electric machines from a size which will not overheat to that which is commercially practical, considerable judgment must be exercised and the results of actual operation analyzed. Unlike trolley-electric motive power, where schedules, grades and tonnages are rather well defined, the self-propelled locomotive must be built to fit an extremely wide range of operating conditions. Experience has shown that the practical minimums for the continuous tractive-force ratings of the electric equipment should approximate the values shown in Table II.

Table II. Preferred Minimum Continuous Tractive-Force Rating

Type of Service	Per Cent of Weight on Drivers
Switching service	13 to 15
High-speed passenger service	11 to 12
Medium-speed passenger service	15 to 16
Low-speed passenger service	17 to 18
High-speed freight service	14 to 15
Medium-speed freight service	17 to 18
Drag freight or transfers	20 to 22

For greatest utility, an electric locomotive must be given as high a tonnage-hauling rating as possible within the safe temperature limits of the electric motors and generators. The maximum tonnage rating of a mechanically driven locomotive for any section of a railroad is that load which can be hauled over the worst grade of that section without stalling. If this tonnage is exceeded and the train stalls, no harm is done to the motive power. This method of rating is not practicable when electric drive is used, for tractive-force values considerably in excess of the continuous rating may be developed without stalling, and correspondingly high ultimate temperature of the electric machinery may be reached. Thus, to determine the maximum tonnage rating of an electric locomotive, calculations or a test must be made to find the peak electric-equipment temperatures when negotiating the worst grades. Such calculations may involve short-time ratings.

Short-time ratings of electric locomotives must be applied with great care in establishing the tonnage-hauling capacity of a locomotive. Even though ample margins are allowed to insure safe temperatures of equipment under ordinary operating conditions, there are many unforeseen circumstances which may require more tractive force than estimated and thus increase the heating beyond safe limits, such as dragging train brakes, inaccurate estimate of train weight, excess proportion of high-resistance cars in the train, or deliberate overloading by uninstructed personnel. Where short-time ratings must be employed to keep within temperature limits, there is always considerable risk of exceeding these if anything goes wrong. For this reason, it is much safer to establish tonnage-hauling ratings for the longer grade zones upon the basis of the continuous tractive-force rating rather than on short-time values. Actual experience has shown that this results in increased operating reliability and reduced electrical repair expense.

Electrical Loading of Prime Movers

In the foregoing, a number of factors involved in the design of the self-propelled electric locomotive have been discussed, including the main electric components, the number of traction motors, the method of driving axles, and the traction motor capacity. Another very essential element to the success of this type of power is the system of control, by means of which full advantage may be taken of all of the power available whenever it becomes desirable to do so, but at the same time limits this load to the capabilities of the prime mover.

One of the important characteristics of a trolley-electric (or third-rail-electric) locomotive is the possible utilization of a relatively unlimited amount of power for propulsion purpose. In any self-propelled unit, the prime mover has a maximum output, usually varying somewhat with the mechanical condition of the plant and with atmospheric changes. Since this power is limited and is usually far below that which could be effectively utilized for propulsion, it is essential that the full available capacity of the prime mover be obtained when needed, whatever its output may be. Moreover, the determination of how much power the prime mover can develop safely should be automatic and not require judgment by the operator.

Various types of power plants—the gasoline engine, the Diesel engine, the steam boiler and steam turbine, and the gas turbine—have different limitations of their maximum capacity. The effect of an overload on a gasoline engine is to reduce its speed but not necessarily to stall it, whereas such an overload on a Diesel engine will usually stall it (assuming constant safe maximum fuel input).

The steam turbine, however, is not harmed when reasonable overloads are applied, and with a limited amount of excess energy stored in the steam boiler, such plants are capable of delivering more than their rated output for a short length of time without harmful effect. Gas turbine plants, being limited by gas temperature and blade materials, will probably not be given any overload factor until experience with such machines shows that overload ratings are permissible. Atmospheric conditions, however, effect big changes in its power output.

Automatic load regulation has attained its highest development in connection with Diesel-electric motive power. An essential of any such control system is simplicity, since adjustments often are made of equipment repaired by railroad personnel who are not trained electrical engineers. It generally has been found expedient to use the engine governor position as an indication of engine-loading conditions, since a tendency to admit more than full fuel means an overload, and action to reduce the fuel below the maximum allowable indicates an underload. Using the governor, then, to initiate action of the load control system, eliminates an extra device for this purpose and promotes simplicity. Full output of the engine is also assured, since the governor action always compares the full capability of the engine against the applied electric load. Such a load control system acts to vary the field strength of the main generator until the volt-ampere output of the generator corresponds to the power input.

In general, internal combustion engines should not be loaded to full torque at reduced engine speeds. Almost all modern control systems for Diesel-electric motive power take cognizance of this, applying electric load at very low torque at engine idling speed, and gradually building up to full torque only when the engine reaches the range of its full operating speed. This is illustrated by the diagram shown in Figure 3.

Traction Motor Connections

No comment need be made on the use of the series-type traction motors for railroad propulsion, because it is well known that their self-adjusting characteristics make them ideal for meeting the extremely variable tractive-force requirements of such service. However, the method of connecting them electrically to the source of power has a direct bearing on the operation of the locomotive.

In the case of a d-c trolley-electric locomotive, which uses motors similar in type to those of a self-propelled electric locomotive, the voltage of the system is relatively constant. To apply low voltage to the motors for starting and then to increase this for accelerating, means that resistance must be inserted in the motor circuits and then cut out in a series of steps until full operating voltage is impressed across the motors. Since the power loss in such resistors is a function of the square of the current value, it is usually expedient to connect the motors first in series relation to reduce the total current fed to the motors and the resultant high resistor loss, and then, when full voltage is impressed across them grouped in this manner, reinsert resistance and change the grouping to a parallel relationship. In this manner, accelerating losses in the resistors are reduced.

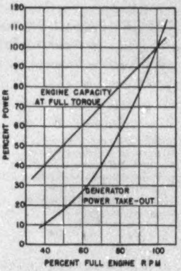

Figure 3. Diesel engine loading at reduced engine speeds

With the variable-voltage generator of a self-propelled locomotive, no accelerating resistor losses are involved. Under these circumstances, it is not necessary to connect motors first in series and then in parallel relationship. Nevertheless, several locomotive builders do resort to this practice, since it enables them to effect a slight reduction in generator size. However, by retaining a permanent relationship throughout the locomotive speed range, several important operating advantages are gained, which weigh heavily toward the adoption of this scheme of connections. Among these are:

1. Simplification of the control. The operator's attention is not distracted by the necessity for a change of connections at specified speeds or current values.

2. Power application is continuous and smooth. A change in traction motor connections is inevitably associated with a momentary unbalance of tractive force between groups of motors, causing rough handling of a train.

3. The possibility of overloading a generator is reduced. With series to parallel control, it is possible to draw excessive current from a generator with motors connected in parallel when they should have been series connected.

4. The smooth control of permanent motor connections reduces the tendency of wheels to slip.

In order to procure the maximum-tractive-force characteristics of a locomotive, it is customary to gear the traction motors with the maximum reduction which still will insure safe motor operation at the maximum permissible locomotive speed. With such gearing, the locomotive speed is usually low at the time that the maximum design voltage is impressed across each motor. In order to increase the locomotive speed, it is customary to weaken the traction-motor field strength by tapping or shunting the field windings in one or more steps. With a trolley-electric or third-rail-electric locomotive, the amount that the fields may be weakened is governed by the imminent possibility of sudden and violent rises in the voltage of the power supply system, which tends to cause motors to flash. Since such surges are not characteristic of an individual power plant, relatively weaker fields may be employed for self-propelled motive power, thus increasing the range of locomotive speed over which full power may be utilized.

Dynamic Braking

Dynamic braking is a system of electric braking in which the traction motors of an electric motive-power unit, when used as generators, convert the kinetic energy of the unit and its train into electric energy, thereby exerting a retarding force. This system has been used rather extensively with self-propelled electric locomotives as a by-product of electric propulsion, and has been found to be very useful for assisting the train brakes in descending long and steep grades at selected speeds. Its application for normal train decelerations when making a stop, however, has not been too popular because of the increased complication of electric circuits.

Dynamic braking is effected by separating the motor armature circuits from the field circuits, and by controlling the field excitation to adjust the voltage generated by the traction motor armatures to that which is required. In self-propelled electric motive power, the armatures are usually connected to a resistor for conversion of the electric energy into heat energy which is dissipated in the surrounding air. The generator of the power plant, being variable in voltage, is

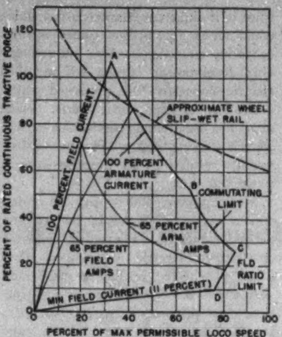

Figure 4. Dynamic braking envelope, resistance braking, fixed resistance value

an excellent source of power for excitation of the field circuits.

Many operating men are unfamiliar with the possible effective range of dynamic braking and expect full braking to be obtained regardless of the locomotive speed. As a matter of fact, such braking is subject to several limitations which allow full braking effect to be exerted over a relatively narrow operating speed range.

One of the prime limitations, of course, arises from the necessity of maintaining the current values through the motor armatures and through their fields, within limits which will not overheat the equipment. Another requirement is that the voltage generated by the armatures be held within accepted limits to reduce the possibility of insulation failures. A third consideration is the commutating characteristics of motors at high speeds when large currents are passed through the armatures; while a fourth limitation is the permissible ratio between the armature and the field currents, as established by the machine stability against flashing. All of these delineate the dynamic braking characteristics in terms of speed and tractive force.

Figure 4 shows a typical dynamic braking envelope of a Diesel-electric locomotive, wherein a single fixed value of dynamic braking resistance is provided. The curve from *A* to *B* is for continuous-rated armature amperes, the shape being determined by the maximum safe generated voltage. From *B* to *C*, the armature amperes must be reduced progressively as the speed rises because of the commutation characteristics at high amperes and high speeds. From *C* to *D*, a greater ratio of armature amperes to field amperes causes instability and possible flashing, while the line from *D* to *O* is the minimum desirable field current for stable control. The curve from *O* to *A* shows the rise in armature amperes with speed for a fixed (maximum) field current.

The dynamic braking characteristics of a locomotive at speeds above that of point *A* are somewhat inflexible, and are fixed by the characteristics of the electric traction motors. However, by reducing the value of the braking resistor, the curve *O–A* may be tipped upward and the braking effect increased at lower locomotive speeds. To reduce this in steps, of course, requires additional control equipment and is seldom found to be expedient for self-propelled motive power.

The efficacy of dynamic braking, as compared to the maximum braking which might be applied, is indicated by an approximate adhesion (wheel slip) curve drawn to the same co-ordinates. With the fixed value of braking resistance selected for illustration (which is in actual operation at present), full braking effect can be obtained only over 11 per cent of the locomotive speed range, or from 29 per cent to 40 per cent of the maximum permissible speed. Above 40 per cent and below 29 per cent speed, the braking force falls away rapidly from the curve which shows the maximum permissible braking as determined by wheel slippage. However, this envelope gives very satisfactory performance under heavy grade conditions when assisted by the train brakes. Care must be taken, however, to see that the locomotive brakes are not applied when braking dynamically, as the adhesive limit may be exceeded.

Resistance braking has had much wider application on Diesel-electric locomotives than on any other type of railroad motive power and has made the railroads conscious of this additional advantage of the electric locomotive. When dynamic braking is incorporated in trolley-electric locomotives, a regenerative type is normally applied so that the regenerated power may be returned to the power system, thereby increasing the operating economy. In most cases, this complicates the locomotive control circuits much more than the resistance type of braking used for self-propelled electric locomotives.

Ventilation

The rotating machinery of electric locomotives must be small, of light weight, and of relatively high capacity. This is especially true of the self-propelled electric locomotive, where the power plant and accessories occupy most of the space available above the locomotive deck and the predominance of the swivel-truck type of running gear limits the space for traction motors. In addition, the cost of self-propelled locomotives is high in relation to the reciprocating steam locomotive, which dictates that all production costs must be kept to the minimum. In the interest of low size, weight, and cost, such large capacity machinery must be force ventilated with cool air.

Very little heat is generated in the equipment compartment of an electric locomotive fed from an external power supply, and what little there is can be directed away from the electric motor ventilating systems. The reverse is true of the self-propelled electric locomotive having a power plant, because there is considerable waste heat, and special care must be exercised by both the locomotive builder and the railroad to insure a full supply of cool air at all times.

Accepted practice for self-propelled locomotive generators has been to mount a ventilating fan directly on the armature shaft. Since full load usually coincides with maximum prime-mover speed, full ventilation is available when needed. Blowers for traction motors are separate machines, driven electrically at times but more often directly from the prime mover. When driven electrically, full ventilation may be maintained at all times, but with a direct drive (or its electric equivalent where an engine-driven alternator and induction-motor fan drives are used) the ventilation fluctuates with the prime-mover speed.

As noted, with direct ventilating fan drives, full air volume usually coincides with full equipment heating. There are many times, however, when this is not the case. For instance, when pushing freight cars over a hump in order to classify them, full rated tractive force and equipment ventilation may be required, but, since the train speed is very low (three to four miles per hour), the horsepower requirements are low. In self-propelled electric locomotives, low horsepower is usually developed at low prime-mover speed, under which condition equipment ventilation is also low. Another case is in dynamic braking. At times, when full braking force is being developed and armature heat is generated at the full rate, the generator speed and consequently the traction motor ventilation is usually low, since only the power for energizing field circuits is taken from this source. These two cases illustrate the need for thorough consideration of the equipment ventilation problem in the design and application of self-propelled electric locomotives.

The operating personnel of the railroads is often neglectful of the equipment ventilating equipment. Fan drive belts may be loose and slipping, air passages may be partially obstructed so that hot air is taken from the engine room instead of from outside, or air connectors to the motors may leak. Any such conditions which tend to increase the temperature of ventilating air or reduce its volume are an invitation to failure in service and to increased equipment repair expense.

Improvements of Details

The tremendous growth in the use of electric motive power within the past 12 years has spurred the development of many details of electric equipment. Roller-type armature bearings are used almost invariably in modern motors and generators, while the felt-wick lubricator has replaced wool-waste packing for many types of bearings. Motors and generators for self-propelled electric motive power, not being subject to high voltage surges or lightning, need not be insulated as heavily as those for trolley-electric locomotives, thus leaving more space for copper. The use of fabricated steel frames, wedged armatures, non-magnetic bands, and improved copper sections have assisted greatly in increasing equipment capacity without increase in weight and size. Technological improvements of this kind, with a vast background of intense and varied Diesel-electric services, are exerting their influence on the designs of equipment for trolley-electric and third-rail-electric motive power.

Renaissance

Electric motive power has changed considerably in character since the advent of the self-propelled types of locomotives. Seldom are the merits of a high center of gravity now discussed in relation to a locomotive design, nor the necessity of a minimum of unsprung motor weight. Flexible drives between a motor and an axle no longer are considered essential for high-speed service. Swivel-truck designs are commonplace, where articulated-truck construction was once considered imperative for heavy-duty locomotives. Where high horsepower per driving axle was once deemed an accomplishment, the desirability of such construction is now very questionable except for locomotives which may be assigned to specific duties.

Almost all modern electric motive power now is being built with low weight and low horsepower per axle, the total locomotive horsepower required being obtained through the use of an increased number of axles. Since it is usually difficult to extend this to an unlimited number of axles under a single motive-power unit, the result is generally secured by coupling several smaller units together to form a locomotive. Such construction also improves the utilization of individual motive-power units, since one may be easily replaced for inspections or repairs without withdrawal from service of the whole locomotive.

The d-c axle-hung motor with a single, reduction spur-gear drive has proved to be entirely satisfactory for any type of self-propelled locomotive and for all classes of service. This is a definite simplification over many of the older trolley-electric locomotives.

The modern, high ventilation rates, resulting in high capacity with a minimum size and weight, are responsible in part for this result

The release of the electric locomotive from the confines of electrified tracks, by the addition of one or more prime movers to each locomotive, has disclosed some of its inherent characteristics which could not be fully utilized under previous operating conditions. Also, the remarkable development of the self-propelled electric locomotive has promoted standardization of equipment parts, which never has been found practical for trolley-electric locomotives. This has subsequently resulted in an immense savings to the railroads.

Motive-power philosophy has undergone a reversal because of the self-propelled locomotive. Where trolley-electric or third-rail-electric locomotives were fitted to specific operating conditions, with few locomotives of similar construction, mass production has necessitated a standardization of the former, and services are now fitted to the capabilities of these standard sizes of self-propelled units.

This procedure has been found entirely practical. The influence of the railroad operating personnel and the mechanical engineer has also been felt strongly. Instead of complicated electric control equipment, they have advocated, and in fact forced, the adoption of simple circuits and apparatus without loss of reliability. In this respect, modern self-propelled motive power has advanced a long way.

With the construction of new types of prime movers in progress, still further attributes of electric motive power are expected to emerge, especially as technological advances occur. One such improvement in prospect, as an example, is the use of high temperature (class *H*) insulation, which should reduce the service limitations now imposed by the time-temperature factors of commercial electric equipment application.

The electric locomotive, long thought to have reached its zenith, is again leading the way toward improved railroad transportation.

Electric Equipment for Chesapeake and Ohio Railway Company Steam Turbine-Electric Locomotives

C. A. ATWELL
MEMBER AIEE

C. E. BASTON
NONMEMBER AIEE

Synopsis: The successful operation of the three 6,000-hp turbine-electric locomotives that were placed in service by the Chesapeake and Ohio Railway Company in 1948 has demonstrated the reliability and adaptability of this type of coal-burning locomotive.

Several articles giving a general description of these locomotives have been published. It is the purpose of this paper to deal more particularly with the electric equipment used, its special requirements, and resulting performance.

Requirements Imposed by Prime Mover

The electric transmission equipment required for a steam turbine-powered locomotive is similar in many respects to that used on Diesel-electric locomotives. The principal differences are in the main generator and the control equipment. These differences result from the dissimilar speed-torque characteristics of the Diesel engine and the steam turbine. The steam turbine has a shaft speed many times that of the Diesel, will not stall if moderately overloaded, and its horsepower is practically constant over its operating range of speed. A comparison of these fundamental characteristics is shown in Figure 1 on the basis of percentages of full horsepower, torque, and speed. The important differences shown here are that the turbine torque rises rapidly as speed decreases and that its horsepower is much more constant from full speed to "idling" speed. These characteristics determine the way in which the generator must be controlled to properly utilize the power available. In the case of the Diesel-electric, considerable development of generator control devices has been necessary to prevent overloading or speed pull down of the engine. Such overloading is bad not only for engine life but any speed pull down means an almost proportional reduction in horsepower. The generator receiving power from a steam turbine does not need to be controlled to the same degree against speed pull down, since there is very little loss of power as speed is reduced over the operating range, and because operation at reduced speed at full throttle is not harmful to the turbine.

The type of service for which the Chesapeake and Ohio locomotives were built indicated a required net input of 6,000 horsepower to generators for traction. This net input produces approximately 5,000 horsepower at the rail. A turbine speed of 6,000 rpm was chosen to give an economical and reliable turbine design.

Main Generator Construction and Arrangement

The generator armature arrangement selected was determined by a combination of commutation, mechanical, ventilation, and motor grouping requirements. Two double-armature generators direct connected to two gear wheels driven by a turbine shaft pinion, proved to be an advantageous arrangement for meeting these requirements. The two generators are placed side by side in the locomotive and have a symmetrical mechanical relation to the turbine shaft. A 6-to-1 gear reduction gives the moderate speed of 1,000 rpm for the armatures. With 1,500-horsepower input to each armature at 1,000 rpm, good commutation and freedom from flashing are obtained without such special requirements as split-throw armature winding or pole-face compensating winding. Each of the four armatures supplies power to two traction motors in parallel. Four simplified independent power circuits are thus provided, any one of which may be removed temporarily from service without affecting the operation of the others

The two multiple-wound armatures of the double-armature generator are duplicates and are pressed onto a common shaft with the commutators at the ends. A heavy duty self-aligning roller bearing supports the outboard end of this shaft and a flange at the drive end is bolted solidly to the turbine gear flange.

Each armature has its own field structure including eight main and eight commutating poles and coils. The armature punching, coil, and commutator construction is the same as that used extensively on Diesel-electric locomotive generators. The field construction is different from the usual Diesel-electric generator in that a large part of the main field is self-excited and that an auxiliary separately-excited field is provided for external control. Also, no engine starting series field winding is required. The eight brushholders are mounted on an adjustable ring and are of the double-brush type with brushes inclined to the commutator surface. Each brushholder is supported by two sturdy insulated pins and can be adjusted easily in a radial direction.

The double armature arrangement is also advantageous for generator ventilation. The air for forced ventilation of the two generators is supplied from a turbine-driven blower to a duct which leads to the bottom center of each generator frame.

Paper 49-45, recommended by the AIEE land transportation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 10, 1948; made available for printing December 27, 1948.

C. A. Atwell is design engineer and C. E. Baston is control and equipment engineer in the transportation engineering department of the Westinghouse Electric Corporation, East Pittsburgh, Pa.

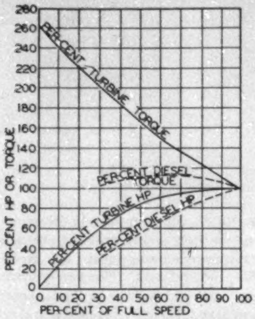

Figure 1. Comparison of speed, horsepower, and torque at full throttle—steam turbine and Diesel engine

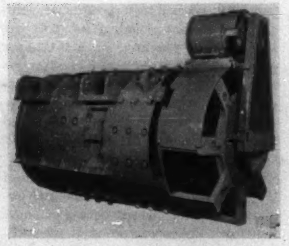

Figure 2. One of the double armature generators with auxiliary generator

From here, the air divides and flows in opposite directions between field coils and through longitudinal ducts in the armatures, past the brushholders and commutators and out through the openings in the end housings. In addition to this, smaller ducts are led from the supply duct underneath the generator frame and directed so they provide a blast of unheated air directly on the lower side of each commutator.

The generator frames are made of exceptionally rigid construction so that they act as stiffening members in the power plant assembly. This frame stiffness, together with a solid vertical mounting plate between the generators, allows a relatively light substructure for the power plant as a whole, yet provides an assembly that is sufficiently rigid to keep all rotating parts in accurate alignment. The entire power plant unit is supported at three points; two trunnions at the turbine end, and a rubber supporting pad under the generator mounting plate. This arrangement insures that stresses set up in the locomotive frame are not transmitted to the power plant assembly to disturb its alignments. A complete double-armature generator, Figure 2, weighs 25,800 pounds or 8.6 pounds per horsepower input.

Generator Performance

Each of the four armatures is rated continuously at 560 volts, 1,860 amperes, 1,000 rpm.

Figure 3 shows the voltage and speed regulation, efficiency, and horsepower input to one generator armature when operating at full throttle. This performance is obtained with the self-excited and separately-excited fields set with minimum external resistance. As mentioned before, the pull down of speed at heavy ampere loads is of little consequence, since the horsepower decreases but little with speed and operation at reduced speed is not harmful to the turbine. For example, at 75 per cent of full speed, the horsepower is still 96 per cent of that at full speed. Very little operating is done at full throttle at ampere loads greater than the continuous ampere rating of 1,860.

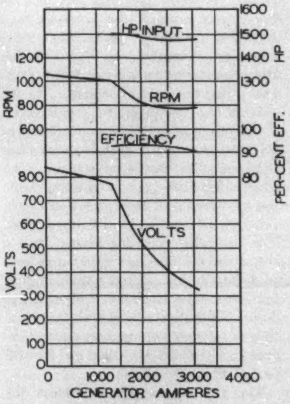

Figure 3. Performance of one generator armature at full turbine throttle

When the locomotive is ready to start, the turbine is idling at 63 per cent speed (3,780 rpm) and the generators are running at 630 rpm. The strength of the separately-excited fields is gradually increased in 11 steps (controller notches) by reducing the external resistance in that field circuit. The turbine speed is also increased slightly from the 6th to the 11th notches. Generator speed is 750 rpm on the 11th notch. As the separate field strength is increased, the self field strength also increases gradually. The separate field notches are small enough to increase gradually the load current supplied to the traction motors. This insures a smooth locomotive start under any condition of load or grade. When full excitation has been applied to the separate field, further movement of the master controller increases the turbine speed further. The self-excited field obtains its supply from the generator terminals through an adjustable resistance. This resistance is controlled automatically in two steps. The first step limits uncontrolled build-up and the second permits full voltage at the higher speeds.

Auxiliary Generator-Exciter

Each main generator is provided with a V-belt driven 9-kw 75-volt 120-ampere self-ventilated auxiliary generator, regulated to give constant voltage from 2,250 to 1,350 rpm. A maximum of 3 kw is required for the separately excited fields of the main generators. These auxiliary generators also supply low-voltage power for meter and indicator lights, control and other auxiliaries such as the mechanical lubricator pump and the air brake system. Either of the two auxiliary generators can supply all of the locomotive low-voltage requirements. Two were installed, however, so that normally they are operating well below their rating. This also made the construction of the right and left hand main generators duplicate at this end. A single regulator controls both auxiliary generators in parallel. Either may be cut out without affecting the operation of the locomotive. Each auxiliary generator weighs 570 pounds.

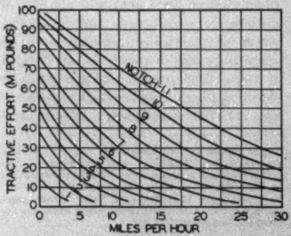

Figure 4. Locomotive performance at reduced turbine speed, showing starting notches

Traction Motors

The eight main driving motors are the Westinghouse type 370-F d-c motors which are widely used on large Diesel-electric locomotives. This motor rates 560 volts, 930 amperes, 750 rpm continuously with full field. This motor is 6-pole, series-wound, force ventilated, axle hung, and is geared to its driving axle with single reduction spur gearing of proved design. The entire motor is constructed for high-speed heavy-duty railway service, and its many successful applications have proved its reliability on both freight and passenger locomotives.

Electrical Control—General Features

The electrical control of a steam turbine electric locomotive bears some resemblance to that of a Diesel-electric locomotive. The differences arise from the different characteristics of the prime mover which has been described in detail before. The idling speed, being approximately 60 per cent of full speed, makes it necessary to apply field excitation to the main generators gradually. Thus the master controller, Figure 7, has two functions. One portion controls the contactors varying the resistance in the separately-excited fields of the main generators and the second portion controls the speed setting of the turbine governor. The field contactors are controlled by a series of contact units operated by cams on the master controller shaft. A cam on this same shaft varies the setting of an air pressure regulator which is connected by means of a control pipe to a spring loaded operating cylinder which is connected by a link to the governor actuating arm. Since no control battery is used on this locomotive, a second cam actuates an air valve which permits bringing the turbine up to the idling speed without control power being available.

Figure 5. Traction motor

An "idle" position is provided between the "off" and "on" positions of the master controller. Steam is admitted to the turbine on this notch and the motor switches are closed but no excitation is applied to the generators. A stop is provided on the master controller so that the handle is stopped in the "idle" position on a normal shut off. To move the handle to the "off" position and stop the turbine, a button in the end of the handle must be pressed.

The idling speed of the turbine is such as to cause the generators to build up as shunt excited machines with the normal field resistance in the circuit. To prevent this, a step of resistance is inserted which is above the critical value. This resistance is cut out of the circuit by means of contactors controlled by a voltage relay whose operating coil is connected across the generator armatures. These relays are set to operate at a voltage somewhat less than the maximum at which time the fields are approaching saturation so that the increased field current does not give a large tractive effort increment.

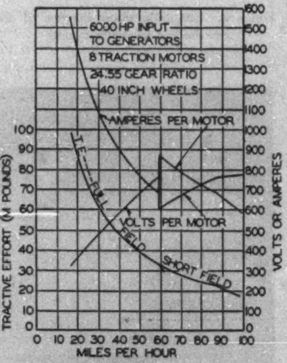

Figure 6. Locomotive performance at full turbine throttle

When the master controller is moved from the idle position to the first notch the field must build up, so the value of the field on the first notch was set to give a moderate tractive effort of 27 pounds per ton of locomotive weight. In practice, the time required for the field to build up softens the control so only a gentle response is obtained on the first notch, making for easy and safe coupling to a train. As the controller is advanced toward the 11th notch, the increments of separately excited field current become gradually smaller as the effect of the shunt field becomes greater. The net result is essentially uniform notching up to the 11th notch. Beyond this point, the quadrant is not provided with notches. The reason for this is that this portion of the master controller merely changes the speed setting of the governor which can be done smoothly without notches. The turbine speed indicator serves as a guide to the engineman in manipulating the master controller.

Figure 7. Master controller used on steam turbine-electric locomotive

Simplified Main Circuits

There is no interconnection between the four armature circuits. Each armature supplies two traction motors connected in parallel, thus the problems encountered in paralleling the generators were avoided, and in addition the cutting out of motors or generator armature is simplified. A small double-pole double-throw knife switch opens the motor switches and the generator fields in each circuit, thus preventing operation of damaged equipment. In the cutout position of this switch a replica resistor duplicating the field is connected across the excitation circuit. This maintains unchanged the other three fields that are connected in parallel with each other and in series with the single field resistor.

An adjustable resistor is connected in series with each separately excited field so as to permit compensating for slight differences in generator and motor characteristics. In practice, it has been found that only slight adjustment of these resistors has been necessary to balance the power equally on the four generators over practically the whole operating range and once set adjustment is permanent.

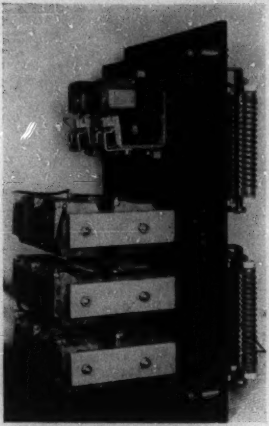

Figure 8. Control panel for self-excited fields of main generators

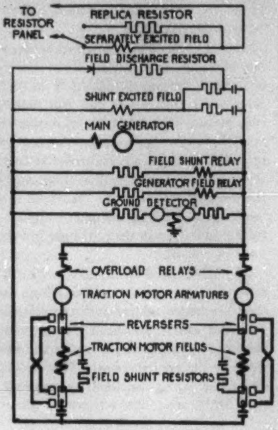

Figure 9. Schematic wiring diagram of one of the four generator circuits

One step of field shunting is provided by a noninductive resistance connected across the traction motor fields by an electro-pneumatic switch. This switch is controlled by a voltage relay connected across the generator armature.

Protection Provided Against Grounds, Overloads, and Wheel Slippage

The self excited fields of each main generator are controlled through a panel, Figure 8, on which are mounted the resistors on the back and the contactors and a Rectox unit on the front. This Rectox unit permits field discharge current to flow through the resistor but prevents any current flow through the field discharge resistor under normal conditions. A relatively low value of discharge resistance may thus be used to provide ample protection from inductive "kick" when the field current is suddenly decreased or the circuit opened.

Overload protection of the electric equipment is accomplished by relays that are arranged to de-energize the emergency trip valve thus shutting down the turbine without interrupting the load.

The parallel connection of the traction motors minimizes the effect of wheel slippage, but a slip relay is provided connected between the two traction motors which are connected to the same generator armature. The relay coil connection is made at the junction of the field and armature leads in each motor circuit. As long as the counter electromotive force, and consequently the speed of the two motors is equal, no current passes through the relay. If a wheel slips, the counter electromotive force of its motor increases and a current passes through the relay coil causing it to close its contacts and causes a warning buzzer to sound. It does not shut off or reduce power.

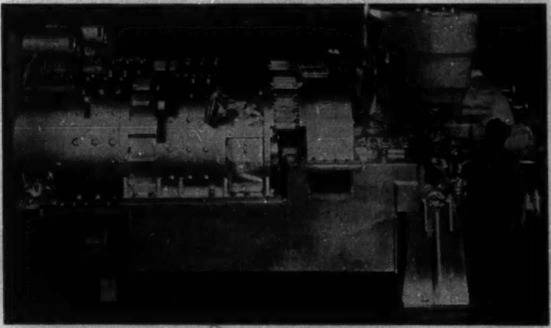

Figure 10. Side view showing mounting trunnions and foot of power plant assembly

The main and control circuits are not solidly grounded, but a simple ground detector is installed which provides a phantom ground midway between the positive and negative busses. This reduces the voltage strain and provides an indication but does not cause a locomotive failure when an accidental ground occurs. This permits the fault to be located and repaired before a second ground could occur and disable the locomotive.

From the diagram, Figure 9, which shows the main circuit of a single armature, the simplicity of which is readily apparent, it can be seen that the circuits involve a minimum of apparatus, the connections of which can be understood readily by the maintenance forces.

Conclusion

The electric equipment for these locomotives employs generators, motors, and control that were designed and built on well-known and proved electrical and mechanical principles. That these principles have been combined in a way especially suited to a steam turbine-powered locomotive of high horsepower is shown by the highly successful performance of this equipment in service.

Selenium Rectifiers in Motor Vehicle Power Systems

GLEN RAMSEY
MEMBER AIEE

FOR A GREAT many years, the electric power for automobiles, trucks, and busses, has come from d-c generators, and from storage batteries charged by these generators. Until recently, the capacity and performance of power systems of this kind has been satisfactory.

The progress in automotive research and development can be measured largely by the increases in electric load which these developments have brought about. Double horns; sealed-beam headlights; additional tail, parking, direction, and interior lights; radios; heaters; fuel pumps; and windshield defrosters are only a few examples.

Up to certain limits, increased load can be met by increasing the size of the battery, the generator, or both. Increasing generator capacity, of course, involves a problem of regulating the charge to the battery. Regulation of the generator field began in an experimental way as early as 1913. However, the present type of vibrating voltage regulator, which was one of the most important developments in automotive electric systems, did not come into general use until 1935.

It is interesting to note that the 1913 Cadillac had a voltage regulator which consisted of a mercury switch operated by a voltage coil solenoid. This regulator was not too satisfactory over the rough roads of that time. In 1914, it was replaced by a governor mechanism, which controlled the generator field current according to the engine speed. During World War I, vibrating-type regulators were built for special purposes, including some Liberty aircraft engines. About 1922, vibrating-type regulators for busses became available. Work was begun to adapt this type of regulator for automobile service in 1926. The "third brush" control, introduced by the Leece-Neville Company in 1914, was in general use at that time, and was used on some makes of cars until 1938.

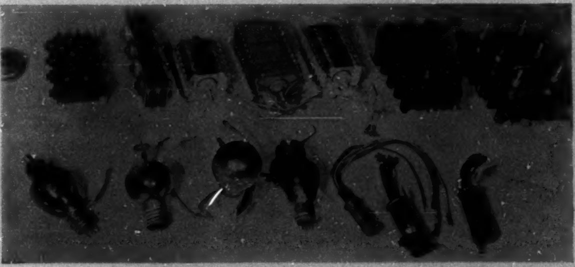
As the electric loads increased, the electric system became more complicated, temperamental, and critical; most of this focused directly upon voltage regulation. High voltage was detrimental to lamp, radio tube, and electric-contact life; low voltage resulted in poor operation of all electric equipment. Unfortunately, most of the increased load was of the type which might be operated whether the engine was idling or running at normal speed. Above certain load limits, it becomes difficult to provide adequate voltage regulation over a wide range of motor speeds and load variations. These problems became especially acute in busses, trucks, police cars with 2-way radio systems, and taxicabs.

To meet these problems, a new approach has been taken—a new electric system consisting of a 3-phase alternator, a voltage regulator, and a rectifier. It might be stated more correctly that the system is new, but the approach has been gradual.

In about 1935, Chrysler Corporation proposed and patented such a system, consisting of a single-phase belt-driven inductor alternator, a voltage regulator, and a rectifier. Tests were made with a number of different types of rectifiers, Figure 1: copper oxide, copper sulphide, mercury vapor, tungar, and others. Several types of inductor alternators were designed, built, and tested, see Figure 2.

In 1936, a flywheel-type of inductor alternator was considered and designed, along with some seven other designs, including a 2-phase system. The increased efficiency offered by the 2-phase system compared to single phase, led to work on a 3-phase inductor alternator. Figure 3

Figure 1. Some of the copper oxide, copper sulphide, mercury vapor, and tungar rectifiers used in early tests with autmotive alternator-rectifier systems



Paper 49-46, recommended by the AIEE land transportation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, January 31–February 4, 1949. Manuscript submitted October 13, 1948; made available for printing January 10, 1949.

GLEN RAMSEY is chief engineer of the rectifier division of Fansteel Metallurgical Corporation, North Chicago, Ill.

The author expresses his sincere appreciation for the assistance rendered by Gilbert C. Goode, F. J. Finkenauer, Jr., and O. E. Bowlus of Chrysler Corporation in collecting information on early history of the system; to B. M. Leece, S. Floyd Stewart, and A. D. Gilchrist of the Leece-Neville Company for information on present systems being manufactured, and also for assistance on the history of regulators; and to W. J. Rady and J. T. Fitzsimmons of Delco-Remy division, General Motors Corporation, for historical information on regulators.

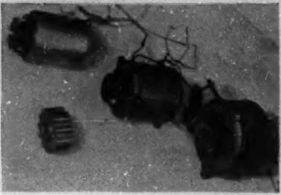


Figure 2. Typical single-phase belt-driven inductor alternators built and tested about 1935

illustrates one of the early flywheel-type single-phase units. Tests on a 3-phase system were made by the Chrysler Corporation, using copper oxide, copper sulphide, and selenium rectifiers.* At this same time, the company with which the author is associated was requested to supply a tantalum electrolytic rectifier, and it was then (1937) that the author first became aware of the scope of this development.

The flywheel-type inductor alternator proved to be noisy, and work on them was abandoned in favor of belt-driven inductor alternators in 1938. This change reduced the noise level, and resulted in a smaller, more compact inductor alternator, one of which is illustrated in Figure 4. The advantages of the 3-phase inductor alternator-rectifier system over the d-c generator were compactness and immunity to troubles arising from wide speed ranges of operation. The cost, unfortunately, was higher than that of equivalent d-c generator systems, which precluded its use in mass-produced vehicles.

The war stopped Chrysler Corporation's development work on the inductor alternator-rectifier systems. During the war, Chrysler Corporation developed a slip-ring alternator-rectifier system for military aircraft, and a number of these were used experimentally in fighters and bombers. Figure 7 illustrates an aircraft selenium rectifier rated at 200 amperes, 30 volts.

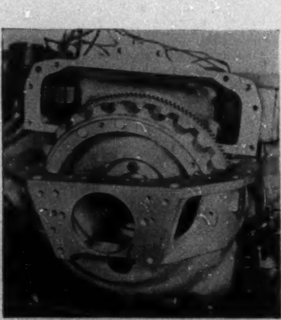

Figure 3. One of the first single-phase flywheel-type inductor alternators for automotive service

At the close of the war, Chrysler Corporation resumed development work on the alternator-rectifier system for automobiles. The important feature of low-speed cut-in was obtained by a simplified and improved field construction. Wartime experience meanwhile, had improved the construction, reduced the over-all dimensions, and lowered the cost of selenium rectifiers. Despite these improvements in the alternator and rectifier, the cost of the complete system did not justify its use in standard automobile production, largely because standard postwar designs do not require loads in excess of present d-c generator capacity.

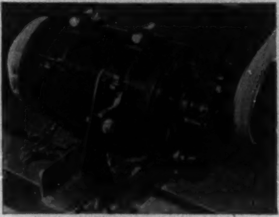

Figure 4. The belt-driven 3-phase inductor alternator proved to be smaller and more compact than the flywheel type

Cost limitations, however, did not keep the alternator-rectifier system out of markets where its use was economical. The Leece-Neville Company, Cleveland, Ohio, having worked with Chrysler Corporation during the war on regulators for the aircraft alternator-rectifier systems, realized the advantages of such a system when applied to vehicular service, and followed postwar developments. Production was begun by the Leece-Neville Company early in 1946, and many thousand units have been installed in busses, trucks, motor cars, and boats.

Early tests indicated, and subsequent tests have established, that for lowest cut-in and highest efficiency, the selenium rectifier is best. Because of lower costs, however, copper-sulphide rectifiers are being used at present in 6-volt systems, even though their characteristics are admitted to be not quite as good as those of selenium rectifiers. While the tantalum rectifier worked satisfactorily in tests, the lower efficiency, the problem of adding water, and the hazards of hydrogen precluded its use.

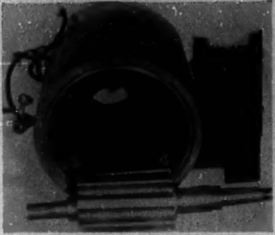

Figure 5. Partly disassembled view of 3-phase inductor alternator shown in Figure 4

At present, all systems of 12 volts or higher manufactured by the Leece-Neville Company employ selenium rectifiers. Selenium rectifiers are used in 6-volt systems only where lower cut-in is desirable or greater efficiency necessary.

The 3-phase alternator which Leece-Neville Company began to manufacture in 1946 was generally similar to the postwar designs developed by Chrysler Corporation. The generator, Figure 9, is a 3-phase, Y-connected, variable frequency 12-pole alternator. Slip rings feed the rotating field. The rotor, Figure 10, consists of two similar 6-legged forgings, making parallel magnetic paths excited by a single coil. Simple assembly and strong construction make the rotors suitable for high-speed operation. The one-turn machine-formed coils of the stator can be delta-connected, but the Y-connected circuit is used for better performance at lower speed, Figure 11.

The frequency in cycles per second of the alternating current generated in this unit is 0.1 times the rotor speed in revolutions per minute. Thus the minimum frequency at which full-load output is

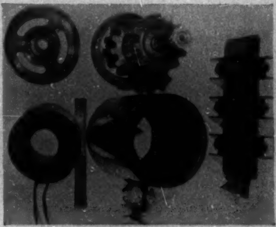

Figure 6. Disassembled view of experimental double-rotor 3-phase inductor alternator

---

* The selenium rectifiers used at this time were imported from Europe. Selenium rectifiers were not manufactured in the United States until 1938.

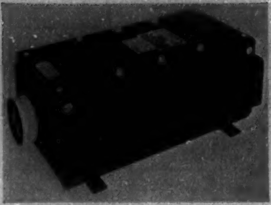

Figure 7. Selenium rectifier, rated 200 amperes at 30 volts, used in conjunction with alternator for aircraft service during the war

obtained in a 12-volt 100-ampere system is approximately 160 cycles. The maximum frequency at full engine speed is not likely to exceed 1,200 cycles. These frequencies are well within the range for best performance of selenium rectifiers.

In comparison with heavy-duty d-c generators, the alternator is very small. Over-all dimensions of the unit illustrated in Figure 9 are $6^{5}/_{8}$ inches diameter by $9\,^{5}/_{32}$ inches long. The weight is approximately 30 pounds.

Excitation of the field coil is accomplished by means of a load relay operated by the ignition switch, thereby exciting the field and connecting the battery to the rectifier. The current drawn by the field is approximately 2.0 amperes. Connections to the field coil are accomplished by brushes to two slip rings. Since the field polarity makes no difference in the operation of the alternator, nor does the direction of rotation, it is possible to rotate the alternator in either direction.

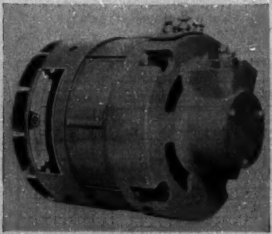

Figure 9. Modern 3-phase Y-connected variable frequency 12-pole alternator

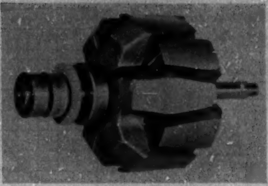

Figure 10. Rotor of alternator, shown in Figure 9, consists of 2 6-legged forgings, making parallel magnetic paths excited by a single coil

The system's control unit, Figure 12, consists of a voltage regulator, current limiter, and load relay. Response to the d-c output from the 3-phase full-wave bridge-type selenium rectifier, Figure 13, effects control by varying the field excitation in the alternator. The load relay is energized through the ignition switch, and is open when the ignition is turned off. In operation, the control-unit voltage-regulator-element primary coil establishes flux to offset mechanical spring tension, and a secondary coil keeps the armature vibrating at a high frequency. A low "point" resistance shunts the first set of operating contacts over a fair portion of the speed and load range of the alternator.

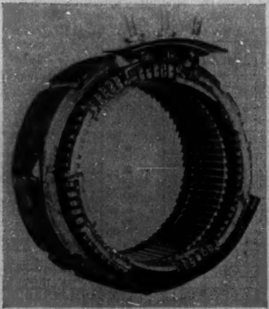

Figure 11. Three-phase Y-connected stator assembly of alternator shown in Figure 9

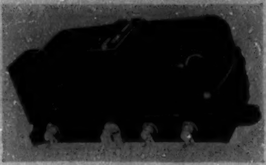

Figure 12. Voltage regulator (14 volts, 100 or 150 amperes) for alternator-rectifier system

When a resistance greater than this value is required to control the system, the regulator armature stops vibrating on the first contact and transfers to the second grounded contact, thereby collapsing the alternator field to the value needed to maintain the correct rectifier

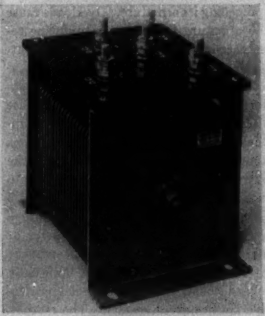

Figure 13. Three-phase full-wave bridge-connected Fansteel selenium rectifier, rated 100 amperes at normal 12 volts, converts the entire output of the alternator into direct current which supplies the load and charges the battery

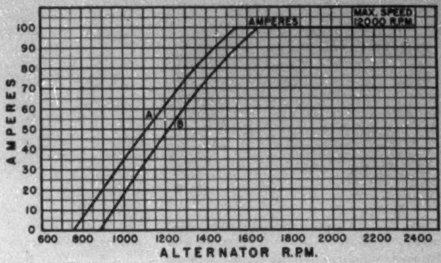

Figure 17. Typical current output of 12-volt 100-ampere alternator-rectifier system at various alternator speeds

Curve *A* shows performance at 12 volts, curve *B* at 14 volts

output voltage. The current limiter coil, in series with the load circuit, establishes flux which offsets spring tension controlling its armature. Overloads cause the armature to vibrate, introducing resistance into the field circuit to limit output current to a safe maximum value.

The selenium rectifier, Figure 13, converts the entire output of the 3-phase alternator into direct current which supplies all the load, with possible exceptions noted subsequently, and charges the battery. The rectifier uses cells 5 by 6 inches in dimension, arranged in 6-1-3 connection in a 3-phase full-wave bridge circuit. It is rated at 100 amperes at normal 12 volts. To withstand the rigors of automotive service, unusually rugged construction and special protective finishes are necessary. The rectifier must not only withstand vibration and mechanical shock, but must be protected against water, salt solution (from icy streets), abrasive dust, and sand. Several types of construction were tried before the design shown in Figure 13 was evolved.

Since the rectifier generates heat and requires ventilation, it is not always practicable to enclose the unit, although this has been done for some types of service. Normally, the rectifier is installed under the hood with the cells in a vertical position, and with the edges of the cells facing the source of ventilation, which may be the radiator fan, an auxiliary electric fan, or other means. Forced cooling permits overloading the rectifier, and permits safe operation in the high ambient temperatures encountered in motor compartments. Under these conditions, rectifier efficiencies range from 75 to 80 per cent. Naturally, the minimum amount of air required to cool the rectifier at full output depends upon the temperature of the cooling air. Figure 16 shows the minimum amount of air, in lineal feet per minute, required for adequate cooling at various air temperatures.

One of the most important advantages of the alternator-rectifier system is its low-speed cut-in. Figure 17 is a typical curve showing output in relation to speed for a 12-volt system. The high over-all efficiency of the alternator-rectifier system makes its use desirable. This efficiency is approximately 65 per cent at rated speed, as shown in Figure 18. (The rectifier efficiency as noted previously is 75 to 80 per cent.) While, under certain favorable conditions, the d-c generator has higher efficiency, the over-all conditions favor the alternator-rectifier system.

For low-speed performance, certainly it has a distinct advantage. At normal engine idling speed, 25 to 50 per cent of the system capacity is obtained, full output is obtained at vehicle speeds of 8 to 12 miles per hour in high gear.

The low-speed performance of the alternator-rectifier system is especially important in vehicles where the electric load is heavy while the unit is idling or running slowly. The city bus is an out-

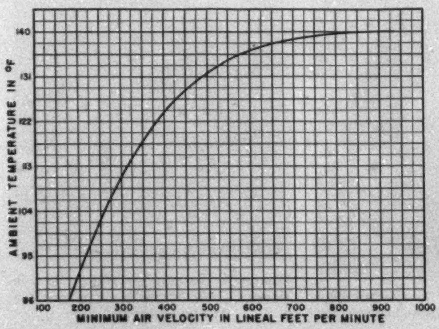

Figure 16. Minimum air velocity (lineal feet per minute) required for adequate cooling of automotive-type selenium rectifier at various air temperatures

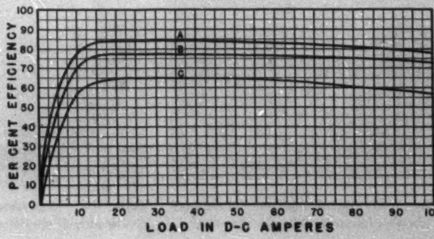

Figure 19. Typical installation of 3-phase alternator and selenium rectifier in a city bus

standing example, with its heavy electric load of lights, fans, and signals. In rush-hour traffic, these busses move slowly, and are stopped for a great portion of the time. Figure 19 illustrates a typical alternator-rectifier installation in a city bus, with sufficient capacity (100 amperes at 12 volts) to carry practically all the lighting load at idling speed. Fire vehicles, taxicabs, police cars, ambulances, utility company trucks, private cars equipped with radio-telephone, cross-country busses and trucks, marine engine plants, and heavy duty tractors also are using alternator-rectifier systems.

Another advantage of this system is that single-phase or 3-phase variable-frequency alternating current is available for windshield heating, fluorescent lighting, and other electric equipment. By means of suitable transformers, almost any desired voltage can be obtained. This offers the automotive engineer the possibility of incorporating both alternating and direct current in the design of new equipment.

While the alternator-rectifier system is confined to applications in a somewhat limited field at the present as compared to mass automobile production, it is believed that in time greater power will be demanded of batteries and generators in regular automobile service. This condition, along with the distinct advantages of this type of system, will lead eventually to much greater use in automobiles.

Discussion

F. Von Voigtlander (The Commonwealth and Southern Corporation, Jackson, Mich.): The author presents a very interesting application of variable-frequency variable-voltage 3-phase a-c generators without the need for mechanical speed-changing or governing devices to make their output useful. The use of a d-c field instead of a permanent magnet field seems surprising, inasmuch as the polarity of the d-c output is dictated by the rectifier connections, and is independent of direction of rotation of the alternator or its field polarity. The reason behind this choice of excitation would be of interest.

While a vibrating-contact regulator is undoubtedly economical and adaptable to regulating the output of this generator to match the requirements of the vehicle battery, the possibilities of output control by d-c-biased transformer action on the a-c generator output would seem to offer greater reliability and freedom from radio interference. The author's comments on methods of regulation would also be appreciated.

A. D. Gilchrist (The Leece-Neville Company, Cleveland, Ohio): We find Ramsey's paper very interesting. It will give other engineers, who are following this subject, a comprehensive review of the work that has been done on automotive rectified a-c battery-charging systems. We believe the following designed details will be of interest as a supplement to this paper. The alternator stator has 72 slots which makes it a two-slot per pole, per phase design. It is wave wound and series Y-connected to generate power at the lowest possible speed. Stator coils are made from rectangular Formex insulated wire, and are machine formed for high-production and low-cost purposes.

The rotor consists of two identical 6-legged Armco forgings, machined to assemble into the 12-pole field design. This design is very simple and mechanically rugged for wide speed range operation. The length to diameter ratio is very important. If the designer does not consider this initially, he may be surprised to find practically no room for the doughnut-shape coil after proportioning his magnetic circuit.

Another important characteristic of this style rotor is the 7-to-1 power ratio between the salient pole-type field and this rotor for the same system performance. Automotive voltage regulators can control only low amounts of field power for good contact life; thus, this field construction contributes a great deal to the outstanding performance of the system.

Commercial vehicle operation today commonly experiences 50 per cent idle engine speed operation. There are conditions where 70 to 75 per cent of the time the engines are idling; thus, ampere-hour or watt-hour calculations of the load versus the generating system capacity are necessary to obtain a reliable vehicle electric system. Therefore, the low-speed performance contributes an important portion of the power during the great amount of idle operation.

Glen Ramsey: Early models of the alternator had experimental permanent magnet fields. They were more difficult to regulate, as brute-force regulation had to be employed in the d-c circuit. This system was discarded in favor of the separately excited field because of cost and reliability. Voltage regulators of the vibrating type have been used with satisfaction for a great many years to control the field current of d-c generators.

Since it is possible to control a considerably greater amount of power in the alternator with the same amount of field current of a given d-c generator, this system of control was adopted. Therefore, the standard-type regulators were adapted to the alternator, with a gain in output in excess of two times.

Some of the other disadvantages of permanent magnet fields are:

In order to get the best low speed performance, higher flux densities are required than are obtainable in a given size with permanent magnet fields.

A permanent-magnet-field alternator has less maximum output for a given structure, over a wide speed range. Naturally, in this type of application, a wide speed range is essential to give desired performance.

Undoubtedly future developments in the art of magnetic amplifiers may produce a regulator of the saturable-reactor type which will be satisfactory. Naturally, such a system would be desirable. However, the size and cost, at the present state of the art, is prohibitive in the automotive industry. Such units are being suggested and developed at the present time, and it is hoped that in time these regulators can be made economical and reliable. In the meantime, the present vibrating-type regulator is being used.

Polar Vector Indicator

THE PROBLEM of determining the magnitude and phase angles of two or more voltages or currents frequently arises in circuit and instrumentation research. An excellent example of such a problem is the design of a feed-back amplifier or servomechanism. In more complex systems, the determination of the effect of changing certain circuit parameters is often as complex and time consuming as the initial analysis required in determining the characteristics and constants of the desired system.

A more elementary, but equally important, problem nearly always is encountered in the teaching of a-c circuit theory. It is customary to define sinusoidal current or voltage variations by means of equations and circle diagrams. This is easily understood by the average student. The transfer of these basic concepts to the use of vectors for the solution of more complex circuit problems, however, often is difficult for the student who has not developed the power of visualizing the meaning of the vector concept.

In view of the above, an electronic device[1] has been developed which has been found to be of great value in the solution of the preceding and similar problems. This device is called a polar vector indicator since it permits the delineation on a cathode-ray-tube screen of the magnitudes and phase angles of as many as three voltages or currents of the same frequency. In the instrument to be described, the frequency may be varied over the range of 15 to 300 cycles per second. Thus, the characteristics of an electric circuit or network may be determined quickly and visually in vector form, as a circuit or network parameter is changed, or as a function of frequency, or both. For the beginning student, this has been found to give meaning to the vector concept. In circuit analysis or research, the device permits simple and rapid determination of the effects of parameter modifications on the characteristics of the system under investigation.

The presentation appears on a cathode-ray-tube screen as a horizontal straight line for the reference voltage and as two dots for the two comparison voltages. By locating the center of the reference line at the center of a polar-co-ordinate system drawn on the cathode-ray-tube face, the magnitudes of the three voltages may be read directly by the length of the line and the radial displacement of the dots. The phase angles between the comparison and reference voltages also may be read directly from the angular displacement of the dots from the reference line.

Basic Circuit

The operation of the polar vector indicator is based on the use of an electronic switching system which permits polar deflections of the cathode-ray-tube spot, of such magnitudes as to indicate the amplitude and phase angle of the voltages or currents of interest. Referring to Figure 1, one of the voltages, generally the input to the device being investigated, is impressed through suitable circuits on the horizontal deflection plates of the cathode-ray tube. This appears as a horizontal line whose center is placed at the origin of a polar-co-ordinate screen. The length of the line is proportional to the amplitude of the impressed voltage. Its phase is chosen as the phase origin. Hence, the phases of the other voltages are established by the zero and 180-degree phase points, marked *B switch closed* and *C switch closed* in Figure 1.

Attention now will be confined to the second voltage input denoted as *B*. For the example of Figure 1, this has been chosen of equal amplitude to the reference voltage *A*, but leading it by 60 degrees. It will be noted that the magnitude of the *B* voltage, at the instant of zero phase of the reference voltage, is applied through the switching system to the vertical plates of the cathode-ray tube. A similar voltage is impressed on the horizontal deflecting plates at the same instant, but with its phase advanced 90 degrees by means of suitable networks in the instrument. The vector sum of the two voltages, illustrated at the right of the figure, is seen to be proportional to the magnitude of the *B* voltage, and its phase angle, for this example, leads the reference voltage by 60 degrees.

Similar statements apply for the third voltage, *C*, except that the phase origin, as far as switching is concerned, is chosen at the 180-degree phase point of the reference voltage. This is necessary in order to separate the *B* and *C* spot deflections from the *A* deflection. As described in the following, it is necessary to provide a 180-degree phase shift in the *C* circuits of the instrument so that phase coherence may be maintained.

Theory of Operation

The theory of the device is extremely simple, and will be given as a further aid in the explanation of the operation of the instrument.

Consider a sinusoidal reference voltage

$$e_A = E_B \sin \omega t$$

where, as usual, e_A indicates the instantaneous value of the reference voltage of angular frequency ω, and E_A is its maximum value, obtained when

$$\omega t = \frac{(2n-1)\pi}{2}$$

where n is a positive integer. Then for

Polar Diagram Showing Addition of Horizontal and Vertical Components to Produce "B" Vector

Figure 1. Polar vector diagram and time sequence of switching

the instantaneous B voltage we may write

$$e_B = E_B \sin(\omega t + \phi_B)$$

where ϕ_B is the phase angle between e_A and e_B.

As indicated on Figure 1, two B deflection voltages are impressed on the cathode-ray tube as e_A goes through zero degrees. The vertical deflection voltage is given by

$$e_{BY} = E_B \sin(\omega t + \phi_B)$$

while the horizontal deflection voltage is given by

$$e_{BX} = E_B \sin\left(\omega t + \phi_B + \frac{\pi}{2}\right)$$
$$= E_B \cos(\omega t + \phi_B)$$

In these relations, ωt is restricted to the values

$$\omega t = 2n\pi$$

with n equal to zero or a positive integer, by the switching action occurring at these times with regard to the reference phase. The phase advance of $\pi/2$ in the X deflection voltage is obtained by a suitable network in the instrument.

The net deflection voltage determining the position of the cathode-ray-tube spot is then

$$e_B' = E_B (\cos \phi_B + j \sin \phi_B)$$

where j is a space operator accounting for the 90-degree position of the deflection plates and ωt has disappeared because of the preceding restriction. Hence, in polar co-ordinates, the net deflection voltage and consequently the deflection obtained is given by

$$e_B' = E_B e^{j \tan^{-1} \frac{\sin \phi_B}{\cos \phi_B}} = E_B e^{j\phi_B}$$

This indicates that the resulting spot deflection is proportional to the magnitude of the B voltage and leads the reference voltage deflection by ϕ_B as desired.

It is evident from Figure 1 that the third voltage, C, may be treated in the same manner, except that the C switches are actuated when $\omega t = (2n - 1)\pi$. An additional 180-degree phase shift in the C channel then provides phase coherence. It will be noted that the deflections proportional to the signals A, B, and C occur at different times. Visual integration is obtained by means of the cathode-ray-tube phosphor, so that the three deflections appear to be simultaneous to the observer.

Block Diagram

The block diagram of the instrument appears in Figure 2. The reference input, A, is applied through a continuously variable attenuator, to a 135-degree phase shift network whose function is described later. The output of the network is applied to a square-wave generator and, through a suitable isolation network which is not shown, to the horizontal-deflection amplifier of the cathode-ray tube.

The output of the square-wave generator is applied to two single-sided multivibrators or triggers through differentiating networks and half-wave rectifiers or clippers. By this means, the B trigger is actuated at the instant the A voltage goes through zero degrees, while the C trigger is actuated at the instant the A voltage goes through 180 degrees. The output of the B trigger actuates the horizontal and vertical B switches, while the output of the C trigger actuates the horizontal and vertical C switches. The outputs of both the B and C triggers are also used to actuate the intensifier amplifier, which is used to brighten the cathode-ray-tube spot during the triggering intervals.

Now consider the B signal circuit. The B signal input is applied through a step attenuator to 135-degree and 225-degree phase-shift networks. It will be noted that the phase difference between the outputs of these two networks is 90 degrees. It will be noted further that, due to the 135-degree network in the reference A circuit, the output of the 135-degree network is ϕ_B ahead of the corresponding point in the A circuit. The output of the 225-degree network is applied through the horizontal B switch to the horizontal-deflection amplifier. The output of the 135-degree network is similarly applied through the vertical B switch to the vertical-deflection amplifier.

Since the B switches are closed only when the reference signal goes through zero degrees, it is evident that the B deflection voltages will be applied only at this time. The trigger pulse, actuating the switches, is approximately 50 microseconds long. Thus, the B deflection voltages are applied for 300 × 360 × 50 × 10^{-6}, or 5.4 degree of a 300-cycle signal. This becomes 0.27 degree at 15 cycles, the lower frequency limit of the present equipment.

Figure 2. Block diagram of the indicator

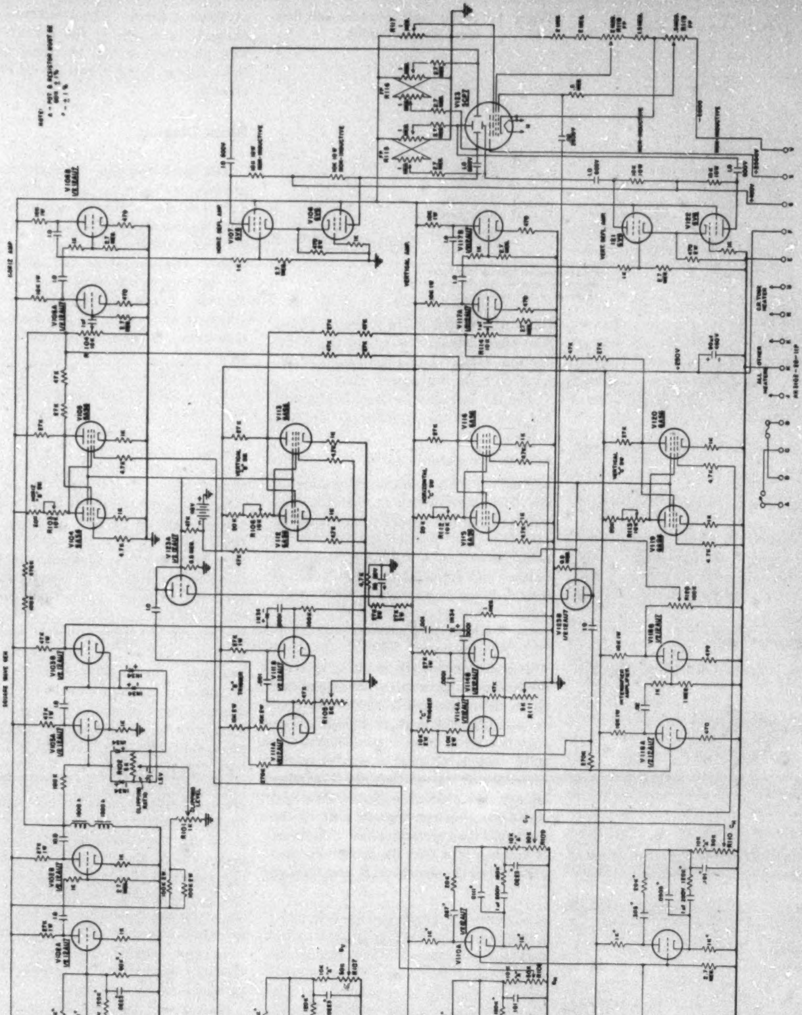

Figure 3. Complete schematic diagram

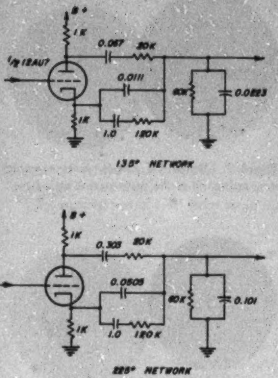

Figure 4. Phase shifting networks

The *C*-signal circuit is essentially the same as the *B* circuit except for the addition of the 180-degree phase inverter before the two phase-shift networks. Since the *C* switches close when the reference voltage goes through 180 degrees, this provides a common phase origin for the three inputs.

Schematic Diagram

The schematic diagram of the instrument appears in Figure 3. Certain portions of the complete schematic diagram have been drawn separately to aid in the description of the operation of the device, and appear in Figures 4, 5, 6, and 7.

Referring to Figure 3, the *A* input is applied through a phase inverter to a 3-section phase-shift network. The *B* input is applied to two phase inverters and associated phase-shift networks. The *C* input is connected through a 180-degree phase inverter to two phase inverters and associated phase-shift networks.

The phase shift networks, Figure 4, are of particular interest since they permit the successful operation of the equipment over a 20-to-1 frequency range without adjustment. It was mentioned in the theory section that a phase difference of 90 degrees is required between the horizontal and vertical deflection voltages in both the *B* and *C* channels. Dome[2] has described a method of satisfying these requirements by utilizing the difference in phase between two networks, so that the difference phase-frequency characteristic is approximately constant at 90 degrees over the preceding frequency range. The networks illustrated in Figure 4 provide a difference in phase shift of 90 degrees ± 3 degrees over the frequency range of 15 to 300 cycles per second.

The accurate determination of the zero-degree and 180-degree phase points of the reference signal is made possible, in a simple manner, with the aid of the rather unconventional square-wave generator or regenerative squarer, which is shown in detail in Figure 5. This circuit, designed by one of the authors, will be described in detail elsewhere.

The regenerative squarer provides a square-wave output for any input voltage between 5 and 50 volts. The switching time is less than five microseconds and switching consequently occurs within one-half degree of the zero-degree and 180-degree reference voltage points, for the highest frequency within the range of the instrument. The squarer consists of a 2-stage triode amplifier with regeneration occurring because of a common cathode resistor. Crystal diodes limit the positive and negative voltage swings at both grids, thereby producing a square-wave output.

It was found necessary to provide adjustments for both the clipping level, total limiter bias, and clipping ratio, ratio of positive to negative limiter bias, to reduce the switching error to the preceding figure. It is further necessary to utilize a low-resistance driving source for best operation. This is the purpose of the two series chokes used as the load for the amplifier driving the squarer, Figure 3. The circuit will oscillate at zero input, so it is necessary to utilize circuit parameters resulting in an oscillation frequency less than the lowest signal frequency to avoid ambiguity in the square wave produced.

The reference signal voltage utilized for driving the square wave generator is also applied, through a suitable isolation network, to the horizontal-deflection amplifiers. The resulting horizontal cathode-ray-tube deflection is proportional to twice the amplitude of the reference signal, and, as mentioned before, is chosen to have zero reference phase angle.

The output of the square-wave generator is applied to the inputs of the two trigger circuits through crystal diodes and differentiating networks. The crystal diodes and trigger inputs are connected so that the trigger circuit driving the *B*-channel electronic switches, is actuated by the positive pulse on the trigger input which occurs when the reference signal goes through zero degrees. Similarly, the trigger circuit driving the *C*-channel electronic switches, is actuated by the negative pulse on the trigger input which occurs when the reference signal goes through 180 degrees.

The trigger circuits[3] are quite conventional, as will be noted by referring to Figure 6, the *B*-channel trigger. The trigger output pulse length is adjusted to about 50 microseconds. Ideally, the trigger pulse length should be inversely proportional to the signal frequency, so that the electronic switch closure time would be constant in angular measure. The added circuit complications were not deemed worth-while in the present instrument. The results obtained with the instrument tend to bear out this assumption.

The outputs of the two triggers are combined through suitable isolation networks, and drive the input to the intensifier amplifier. The pulse output of either trigger is thus used to brighten the cathode-ray-tube trace.

Two other outputs from the *B*- and *C*-channel triggers are utilized to actuate the respective electronic switches in these two channels through delayed d-c restorers. Confining initial attention to the *B* channel, it will be noted that the output of the *B*, 225-degree, phase-shift network is applied to the control grid of the vertical *B* switch. The output of the *B*, 135-

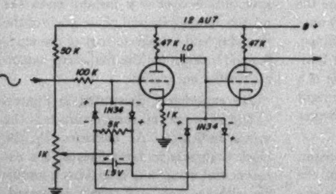

Figure 5 (left). Regenerative squarer showing input and output wave shapes

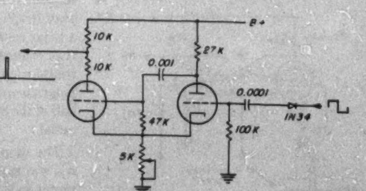
Figure 6 (right). Trigger circuit with differentiator for B channel



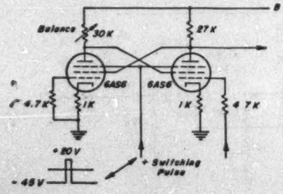
degree, phase-shift network is applied to the control grid of the horizontal *B* switch. Thus, upon actuation of the *B* trigger at the zero-degree point of the reference signal, the two *B*-channel switches are closed, permitting application of the vertical and horizontal *B*-channel outputs to the respective cathode-ray-tube deflection amplifiers during the trigger output pulse interval.

The type of transientless electronic switch[4] utilized contributed greatly to the success of the equipment. Referring to Figure 7, switching is accomplished by applying positive pulses to the suppressor grids of two tubes, one an amplifier and the other a sleeper. The plate current of both tubes is normally cut off by means of a large negative suppressor grid bias. As the bias is removed, by means of a switching pulse, and the plate current of both tubes increases, the negative transconductance from the suppressor to the screen grid of the sleeper tube matches the positive transconductance from suppressor grid to the plate of the amplifier tube. Consequently, the switching transients are balanced out, and the switching amplifier is turned on without distorting the amplified output obtained from the input signal.

Again referring to Figure 3, it will be noted that the *C* channel is identical to the *B* channel except for the addition of the input 180-degree phase-shift stage. The remaining portions of the circuit, such as the deflection amplifiers, cathode-ray-tube circuits, and so forth, are entirely conventional and require no further discussion. It will be noted that the power supply, also conventional, is not shown in the figure.

The complete instrument, without power supply, appears in Figure 8. As mentioned previously, the present model of the equipment is capable of operating over the power frequency range, from 15 to 300 cycles per second, without readjustment. The permissible input voltage range on any of the three channels is from 0.5 to 500 volts rms. The accuracy of the phase measurement is ±3 degrees, while the amplitude accuracy is ±10 per cent.

Figure 7. Electronic switch



Results

Several simple experiments were devised to illustrate the operation of the instrument. Figures 9, 10, 11, and 12 incorporate the schematic diagram of the experimental setups on the right, with time-exposure photographs of the cathode-ray-tube face of the vector indicator appearing at the left. Each photograph indicates the locus of certain voltages for given circuit parameters as one of the parameters or the applied signal frequency is changed. All photographs were obtained during 10-second exposures. It has been found that similar visual results may be obtained by utilizing a long persistence screen in the vector-indicator cathode-ray tube.

Referring to Figure 9, a fixed-frequency, constant-amplitude voltage, E_1, was impressed across a series resistance-capacitance circuit and was also applied to the reference, *A*, channel of the vector indicator. The resulting vector-indicator deflection appears as the horizontal straight line on the photograph. The length of the line is proportional to twice the amplitude of E_1. It was found necessary to remove the polar co-ordinate grid, shown in Figure 8, in order to obtain a photographic reproduction suitable for printing. Consequently, it is necessary to visualize the photograph of Figure 9 as projected onto a polar co-ordinate screen. By so doing, it is evident that the center of the horizontal reference line lies at the center of a polar co-ordinate system, with the right half of the line lying along the zero-degree radial.

The drop across the variable resistor, E_R, was applied to the *B* channel of the vector indicator, and the resistance was varied from zero to, essentially, infinity. The resulting voltage locus in amplitude and phase, with reference to E_1, appears as the familiar semicircle whose diameter is equal to the amplitude of E_1.

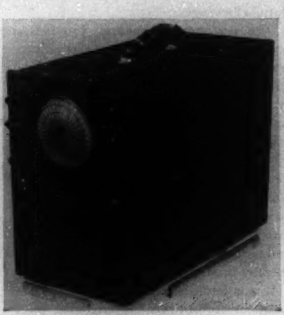


Figure 8. Vector indicator

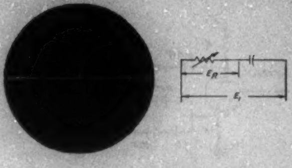

Figure 9. Series R-C circuit, voltage across resistance as the resistance is varied

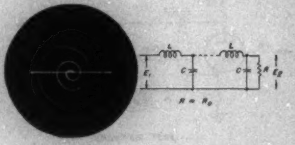

Figure 10. Locus of receiving-end voltage of artificial transmission line, terminated in its characteristic impedance, as the frequency of the input voltage is increased

A somewhat more interesting experiment is illustrated in Figure 10. As indicated by the schematic diagram at the right of the figure, the reference input voltage, E_1, was applied to the sending-end terminals of an artificial line, while the receiving-end terminals of the terminated line were connected to the *B* channel of the vector indicator. A 10-section artificial line terminated in its characteristic impedance was used. The output voltage E_2 was then determined in magnitude and phase, with reference to E_1, as the frequency of the applied voltage was varied, by means of a motor-driven oscillator, over the frequency range of the vector indicator.

As in the previous figure, the horizontal straight line is a measure of the sending-end voltage which was chosen to have zero reference phase. The spiral is the locus of the receiving-end voltage. The spot obtained at any instant gives the relative magnitude and phase angle of the receiving-end voltage to that of the sending-end voltage for the frequency associated with that instant.

The experiment illustrated in Figures 11 and 12 utilizes all three channels of the vector indicator. As indicated by the block diagrams in both figures, the experimental setup was a feed-back amplifier with the feed-back terminals opened.

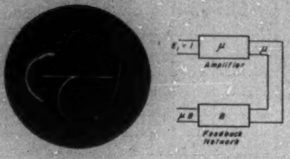

Figure 11. Feed-back amplifier characteristics showing μ and $\mu\beta$. Instability indicated by encirclement of 1, 0° point by $\mu\beta$

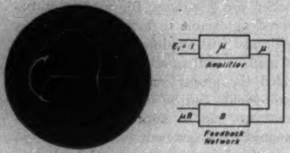

Figure 12. Feed-back amplifier characteristics showing stability resulting from incorporation of suitable notching filter in the β network

The input voltage, E_1, was set equal to unity and the complex amplification, μ, and the complex feed-back voltage, $\mu\beta$, were determined as the frequency of E_1 was varied over the range of the vector indicator.

Referring to Figure 11, the horizontal straight line is the unity-valued input voltage E_1, so that the right-hand end of this line denotes the point 1, zero degrees in the complex plane. The short arc at the left is the locus of μ. A single tube, with a voltage amplification of somewhat greater than unity at the center frequency, was utilized for the amplifier. This is illustrated by the fact that the μ locus passes through 180 degrees beyond the left-hand terminus of the reference line. The large arc is the locus of $\mu\beta$.

A short transmission line was utilized for the feed-back network. This resulted in a large change in $\mu\beta$, when compared with μ, as will be noted in the photograph. It should further be noted that $\mu\beta$ encircles the right-hand end—the 1, zero degrees point on the complex plane—of the reference line. Hence, according to Nyquist's criterion,[5] the feed-back amplifier should oscillate when the feed-back loop is closed. This was found the case.

Figure 12 illustrates the characteristics of the same feed-back amplifier used in obtaining Figure 11, with the feed-back loop open, but with the addition of a suitable notching filter to decrease $\mu\beta$ in the frequency range wherein $\mu\beta$ formerly encircled the point 1, zero degrees. Under this condition, the feed-back amplifier should be stable when the feed-back loop is closed. This was found to hold true.

Conclusion

The polar vector indicator has been found by experience to be an extremely useful tool in teaching and in research. Its great advantage over former methods of determining relative voltages, or currents, and phase angles is the ease and rapidity with which such measurements can be made. For example, the determination of the characteristics illustrated in Figures 11 and 12 by conventional methods would probably require two or three hours. These are obtained with the polar vector indicator in ten seconds. The instrument is particularly valuable when it is desired to investigate effects of parameter changes in a given system.

While the present instrument was designed for the power frequency range of 15 to 300 cycles per second, it would be a relatively simple matter to design a similar device for the lower frequency range commonly required in servomechanisms. It is thought that the instrument could be built to cover the audio frequency range, to 10 kc, by suitable broad-banding and relatively straightforward circuit design.

A Semiempirical Approach to Voltage Dip—with Suddenly Applied Loads on A-C Generators

L. T. ROSENBERG
MEMBER AIEE

THE variation in terminal voltage when load is suddenly applied to an a-c generator is of importance in the selection of machines required to start relatively large motors, to be sure the disturbance will not affect other motors or equipment on the system. It is also of interest when one or more generators are suddenly taken off the system imposing additional loads on the remaining units.

Point by point methods for calculating the voltage time curve, although accurate, have been found tedious and rather exacting. An analytical solution[2] has also been published based on the use of a voltage regulator and an exponential exciter build up curve corresponding to self excitation with little or no saturation in the operating range.

In these methods, the first few cycles are disregarded on the basis that no appreciable restoration of voltage begins within this interval anyway. While this may be substantially true today, developments in electronic and rotating-type regulators may ultimately lend more significance to this period.

The method presented here for determining the decay of voltage is sufficiently simple that the subtransient voltage drop can be included if desired. The exciter voltage build up is expressed by a form of exponential, well adapted to either separate excitation or self excitation with saturation. The equation for the build up of field current under ideal conditions is solved and the results expressed in a convenient single family of curves from which the entire current build up curve may be read directly. It is shown that with proper selection of time constant, this same family of curves may be used with good agreement for the build up of the sustained component of the terminal voltage. Oscillograms, covering tests on a 40,000-kva machine, are presented to show the accuracy to be expected.

Decay of Terminal Voltage

When induction motors or synchronous motors are started, the suddenly applied load may be considered as a short circuit through external impedance. The three components of short circuit current, sustained, transient, and subtransient, will result in three corresponding components of terminal voltage; e_2, e_2', and e_2'' respectively. The terminal voltage with fixed excitation is expressed in terms of these component voltages and the corresponding time constants, suitably corrected for external load, as follows

$$e_t=(e_2''-e_2')\epsilon^{-\frac{t}{T_{d1}''}}+(e_2'-e_2)\epsilon^{-\frac{t}{T_{d1}'}}+e_2 \qquad (1)$$

where

e_t = resulting terminal voltage at time t seconds
T_{d1}'' = corrected subtransient short circuit time constant
T_{d1}' = corrected transient short circuit time constant
e_2'' = generator terminal voltage immediately after the load change assuming generator internal reactance is x_d''
e_2' = the same based on x_d'
e_2 = the same based upon x_d/per unit excitation prior to loading

The calculation of the three voltage components may be done by any convenient method. While the present study and supporting test data are concerned only with static loads applied to an unloaded a-c generator, the method is believed applicable to loaded machines as well, and with modifications, to removal of load as well as addition of load, provided the proper values of the voltage components can be found and the time constants can be approximated for the range of loads involved.

If the initial and acquired loads are both static and linear with voltage, it is shown in Appendix I that the three voltage components can be expressed as

$$e_2,\ e_2',\ \text{or}\ e_2''=\sqrt{\frac{1+2b\sin\theta_1+b^2}{1+2a\sin\theta_2+a^2}} \qquad (2)$$

where

$b=\frac{I_1x_d}{K_1}$, I_1x_d', or I_1x_d'' respectively
I_1 = initial load current (per unit voltage of unity assumed)
K_1 = initial per unit excitation on generator
$\theta_1=\cos^{-1}$ (initial power factor)
$a=\frac{I_2x_d}{K_1}$, I_2x_d', or I_2x_d'' respectively
I_2 = final total load current after full voltage restored
$\theta_2=\text{Cos}^{-1}$ (final power factor)

For no initial load, the numerator under the radical becomes unity, and for the special case of reactive load

$$e_2,\ e_2'\ \text{or}\ e_2''=\frac{1}{1+a} \qquad (3)$$

In Appendix I, the voltages also are derived for initial and acquired loads whose currents and power factors are independent of voltage. This relation is

$$e_2,\ e_2',\ e_2''=\sqrt{\cos^2\theta_1+(b+\sin\theta_1)^2+a^2\cos^2\theta_2}-a\sin\theta_2 \qquad (4)$$

For more complicated loads, determination of the voltage components may be difficult or impossible except by interpolation between values for known

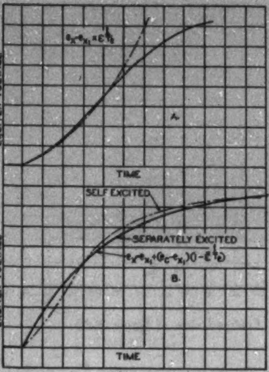

Figure 1. Equations for exciter build-up

(A) Self excited below saturation
(B) With saturation, or separately excited

conditions. Correction of the time constants also becomes increasingly difficult.

Exciter Voltage Build Up

The analytical treatment given previously[8] considered the exciter voltage to rise along a curve

$$e_x = e_{x1}\epsilon^{\frac{t}{T_e'}} \tag{5}$$

As shown in Figure 1(A), this approximates closely the rise for a self-excited exciter before appreciable saturation is reached. The relation used in what follows has the form

$$e_x = e_{x1} + (e_c - e_{x1})\left(1 - \epsilon^{-\frac{t}{T_e}}\right) \tag{6}$$

where

e_c = exciter ceiling voltage with generator field connected across its armature
e_{x1} = initial exciter voltage
T_e = exciter build-up time constant

which is shown in Figure 1(B) to agree closely with the general shape of a separately-excited exciter build-up curve and reasonably well with that of a self-excited exciter, operating well up on its saturation curve. The value of T_e in equation 6 can be found by any one of the three processes described in Appendix II.

Application of Exciter Voltage to Inductive Circuit

When the exciter voltage of the form (6) is impressed on an inductive circuit of constant inductance, L and resistance r, it is shown in Appendix III that the current will follow a curve

$$i_f = i_{f1} + \frac{(e_c - e_{x1})}{r\left(r - \frac{L}{T_e}\right)} \times \left[\left(r - \frac{L}{T_e}\right) - r\epsilon^{-\frac{t}{T_e}} + \frac{L}{T_e}\epsilon^{-\frac{r}{L}t}\right] \tag{7}$$

where

i_f = field current at time t
i_{f1} = initial field current
r = resistance in ohms of the inductive circuit
L = inductance in henrys of inductive circuit
T_e = exciter voltage build up time constant

Fortunately, this expression lends itself readily to quick application in the form of the curves of Figure 2. The initial field current, i_{f1}, is disregarded and the remainder of the right hand member of equation 7 is plotted as a fraction of its final value at $t = \infty$, for various values of time expressed in number of times the circuit time constant, L/r. For each ratio of $L/r/T_e$, only one curve applies. Interpolation between the various curves shown is readily accomplished, to obtain the field current build up for any desired L/r and T_e.

Effect of Eddy Current Paths

It has been shown by Weber,[1] that for magnetic circuits partially solid and partially laminated, the field current and flux do not build up at the same rate due to the eddy current paths in the solid material. In the tests presented herein and on other large machines of both cylindrical and salient pole types the time constant for the actual field current are found to be considerably less than those corresponding to the calculated short circuit time constants corrected for external load.

For the 40,000-kva machine, the actual time constant governing the field current is 2.8 seconds. With this value instead of the calculated T_{d1}' of 5.3 seconds, and with due allowance for the induced initial field current transient assumed to decay in accordance with this same time constant, 2.8 seconds, the generator field current build up obtained from Figure 2 agrees with tests, Figure 5.

The build up of flux on the other hand is found from Figure 2 to agree closely with tests when the calculated transient short circuit time constant, T_{d1}', is used.

Procedure in Determining Voltage-Time Curve

The application of Figure 2 to determine the voltage-time curve may be outlined as follows:

1. Determine the three voltage components of the decay curve and the time constants T_{d1}'' and T_{d1}' and plot.
2. Determine the exciter time constant T_e.
3. Choosing several time values in terms of T_{d1}', select the proper curve on Figure 2

List of Symbols

a = product I_2X, final current times internal generator reactance
b = product I_1X, initial current times internal generator reactance
e_c = exciter ceiling voltage
e_n = exciter nominal voltage
e_x = exciter voltage as a function of time
e_{x1} = initial value of exciter voltage
e_2'' = per unit generator terminal voltage immediately after load change assuming generator internal reactance is x_d'', (subtransient component)
e_2' = same assuming internal reactance is xd', (transient component)
e_2 = same assuming internal reactance is $\frac{x_d}{k_1}$, (sustained component)
$(e_2) = e_2''$, e_2', or e_2
e_t = generator per unit terminal voltage as a function of time
e_g = internal voltage behind subtransient, transient, or synchronous reactance drops
I_1 = per unit initial load current
I_2 = per unit final total load current
i_f = field current
i_{f1} = initial field current, $= \frac{e_{x1}}{r}$
K_1 = initial per unit excitation (based on air gap excitation = 1)
L = inductance of field in henrys, or of inductive circuit
q = ratio of $\frac{e_c - e_n}{e_n}$
r = resistance in ohms of inductive circuit, or field winding
t = time in seconds
T_{d1}'' = time constant governing decay of $(e_2'' - e_2')$, suitably corrected for load
T_{d1}' = time constant governing decay of $(e_2' - e_2)$, suitably corrected for load
T_e = time constant governing the voltage build-up of a separately excited exciter
T_e' = time constant governing the voltage build-up of a self excited exciter (unsaturated)
V = intercept of the straight line defining exciter response with the line $t = 0.5$
X = internal reactance of generator, may be x_d'', x_d', or x_d/K_1
x_d'' = direct axis per unit subtransient reactance
x_d' = direct axis per unit transient reactance
x_d = direct axis per unit synchronous reactance
x_2 = per unit negative sequence reactance
Z_2 = equivalent impedance of the final total load on the generator
ϵ = base of natural logarithms, 2.71828
$\theta_1 = \cos^{-1}$ (initial power factor)
$\theta_2 = \cos^{-1}$ (final load power factor)
∞ = infinity

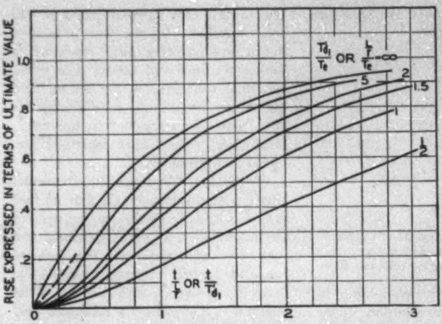

Figure 2(A). Family of build-up curves for field current or terminal voltage

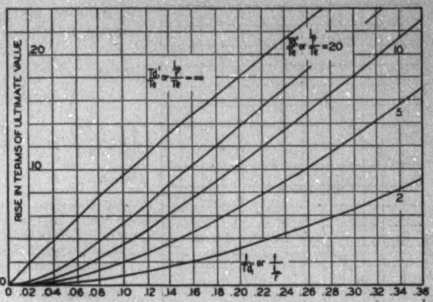

Figure 2(B). Enlarged view of Figure 2(A)

corresponding to the ratio T_{d1}'/T_e and determine the fraction of ultimate rise at each point.

4. These values are then multiplied by the ratio of $(e_c-e_{x1})/e_{x1}$ and by the sustained voltage component, e_2, and the products are added at each instant to the voltage decay curve of step 1, but offset to the right an amount equal to the time required for regulator contacts to close.

Step 4 assumes a linear relation between excitation and sustained component of terminal voltage, except for the substitution of T_{d1}', for the time constant of the actual field current. This means that whatever saturation was present at the initial excitation and sustained voltage, e_2, is assumed to increase proportionately with voltage. The agreement between test and calculated curves, indicates this assumption does not greatly affect the results.

Discussion of Tests

Figure 3, plotted from Film 8 indicates the voltage time curve of the 40,000-kva generator when a 1-ohm per leg reactive load is suddenly thrown on with fixed excitation. The terminal voltage was selected so that one ohm will take full load current at this voltage.

The field current is shown to decay with a time constant of 2.8 seconds, whereas the terminal voltage decay agrees closely with the calculated subtransient time constant of 0.06 second and the calculated transient time constant of 5.3 seconds.

Film 10, Figure 4, shows a sudden change in the voltage regulator control to require a 10 per cent voltage increase. From this film a plot on semilog paper gave a test value of exciter voltage build-up time constant T_e of 0.667 second, which checks the calculated value of 0.615 second obtained from design data fairly well. Figure 6, plotted from Film 15, indicates an even better check of T_e with calculation, in fact almost exact. Film 11, Figure 5, and Film 15, Figure 6, are both for 1-ohm per leg, suddenly applied under the action of a type *J* regulator, whereas Film 13, Figure 7, covers a 2-ohm reactive load, corresponding to 1/2 load current at the initial voltage. Finally, Figure 8, shows a single phase line-to-line load suddenly applied with one ohm in each of the two active phases.

For the single phase test, the voltages, e_2'', e_2', e_2, may be computed by symmetrical components, considering a short circuit through external impedance and solving for the voltage at generator terminals. The line-to-line voltages across the loaded phases by this method, agreed very well with those obtained from equation 3 when the generator reactance is made

$$\frac{x_d''+x^2}{\sqrt{3}},\ \frac{x_d'+x_2}{\sqrt{3}},\ \text{or}\ \frac{\frac{x_d}{k_1}+x_2}{\sqrt{3}}\ \text{respectively.}$$

However, as shown in reference 3, the oscillograms of short-circuit current do not truly indicate the same currents that are calculated by symmetrical components for single-phase faults. The presence of considerable distortion from 5 to 60 cycles flattened the peaks and made the line-to-line voltage wave appear low

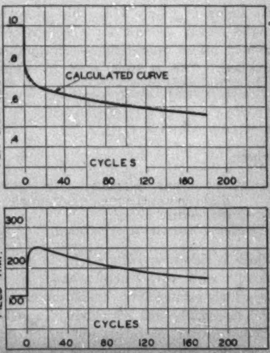

Figure 3 (right). Plot of generator terminal voltage and field current from Film 8, below. Full load thrown on, fixed excitation

[redacted]

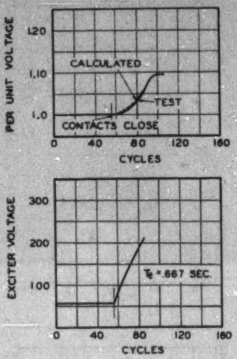

Figure 4 (left). Generator and exciter voltages from Film 10, above. Regulator control suddenly adjusted to raise voltage 10 per cent

in this interval. The line-to-neutral voltage time curve, on the other hand, had very sharp peaks and therefore appears higher than the calculated curve.

Conclusions

A relatively short procedure has been outlined for the calculation of voltage time curves of a-c generators under the control of voltage regulators acting upon separately excited exciters, during sudden load application. The simplifying assumptions permitting the use of the single family of curves to determine restoration of flux are shown by close agreement with tests to be justifiable within the scope of the present study.

Examination of Figure 2, reveals that for separately-excited exciters or self-excited exciters with appreciable saturation, the corrected short-circuit transient time constant is of prime importance in determining the rate of restoration of generator terminal voltage. Another major factor in the recovery time is seen to be the exciter ceiling voltage. The transient reactance is important in determining the maximum voltage dip. The ratio of T_{d1}'/T_e is significant in recovery time below values of 8 or 10, but little can be gained from here up to infinity.

Although the tests were made with the conventional type J contact-making rheostatic voltage regulator, the method of calculation is believed well adapted for the comparison of performance of different types of regulators. A companion paper is in the process of preparation covering tests with the regulex rotating amplifier type of regulator.

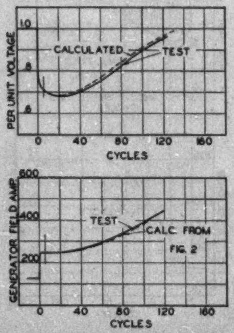

Figure 5 (left). Generator voltage and field current from Film 11, below. Full load thrown on, regulator in operation, first test

Appendix I. Expressions for e_2, e_2', e_2''

Case 1. Initial and acquired load currents and power factors not appreciably changed by the changing voltage. Referring to the vector diagram of Figure 9, e_g is assumed to remain constant as the load is suddenly changed from I_1 to I_2.

$$e_g^2 = I^2 + (I_1X)^2 + 2I_1X \sin\theta_1 = (e_2)^2 + (I_2X)^2 + 2(e_2)I_2X \sin\theta_2.$$

$$(e_2)^2 + (2I_2X \sin\theta_2)(e_2) + [(I_2X)^2 - (I_1X)^2 - 2I_1X \sin\theta_1 - 1^2] = 0.$$

Solving gives

$$(e_2) = \sqrt{(I_2X \sin\theta_2)^2 + 1 + 2I_1X \sin\theta_1 + (I_1X)^2 - (I_2X)^2} - I_2X \sin\theta_2.$$

Now let

$I_2X = a$; $I_1X = b$;

and simplifying

$$(e_2) = \sqrt{\cos^2\theta_1 + (b + \sin\theta_1)^2 - a^2\cos^2\theta_2} - a\sin\theta_2 \tag{4}$$

where (e_2) may be either e_2'' or e_2' from the above considerations for any machine if $X = x_d''$ or x_d'. The analysis is less rigorous for the sustained component e_2 except for cylindrical rotor machines. However, the use of e_2 from these equations with x_d/k_1

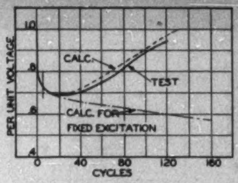

Figure 6 (right). Generator and exciter voltages from Film 15, above. Full load thrown on, second test

substituted for X, has proved sufficiently accurate on both salient and nonsalient pole machines.

Case 2. Both initial and acquired loads linear with voltage. Let I_2 = the final total current that would flow if $e_2 = 1.0$.

Let the final load impedance $= Z_2$, then $I_2 = 1/Z_2$, whereas the actual current after the load change, $I_s = (e_2)/Z_2$. In equation 4 we can therefore substitute $(e_2)I_2$ for the previous I_2 and hence $(e_2)a$ for the previous a, because $a = I_2x$. We may now write

$$(e_2) = \sqrt{\begin{matrix}\cos^2\theta_1 + (b + \sin\theta_1)^2 + \\ (e_2)^2a^2\cos^2\theta_2\end{matrix}} - (e_2)a\sin\theta_2$$

$$(e_2) = \sqrt{\frac{1+2b\sin\theta_1+b^2}{1+2a\sin\theta_2+a^2}} \qquad (2)$$

Appendix II. Method of Calculation of T_e

A. From exciter nominal response. Referring to Figure 10, the response with separate excitation for the main exciter is:

Response $= 2V/e_n$ where V is given by

$$4\int_0^{1/2} e\,dt - 2e_n$$

Response $= \dfrac{8}{e_n}\left[\displaystyle\int_0^{1/2} e\,dt - \frac{e_n}{2}\right]$; substituting $e = e_n + (e_c - e_n)\left(1 - \epsilon^{-\frac{t}{T_e}}\right)$, solving, and letting $\dfrac{e_c - e_n}{e_n} = q$

$$\text{Response} = q\left[8T_e\left(\epsilon^{-\frac{0.5}{T_e}} - 1\right) + 4\right] \qquad (8)$$

This relation is expressed as a curve, Figure 11, from which T_e may be read as a function of the nominal exciter response divided by q.

B. From the exciter voltage build up curve, when entire curve including ceiling voltage is known for the loaded condition. Subtract several ordinates of the exciter build up curve from ceiling voltage and plot differences against time on semilog paper. T_e is the time in seconds for the resulting straight line curve to drop to $1/\epsilon$ times its initial value.

C. From the exciter build up curve when only a portion of the curve is known. Select two time values t_1 and $2t_1$ (see Figure 12) covering the available range of the exciter build up curve or the portion of interest.

Measure the ordinates y_1 and y_2. Then

$$Te = -\frac{t_1}{\log_e\left[\dfrac{y_2}{2y_1} - \sqrt{\dfrac{(y_2)^2}{(2y_1)^2} - \dfrac{y_2}{y_1} + 1}\right]} \qquad (9)$$

Appendix III. Solution of Equation for Field Current Rise

Consider the circuit of Figure 13 with constant inductance and resistance, and an exciter voltage

$$e_x = e_{x1} + (ec - e_{x1})\left(1 - \epsilon^{-\frac{t}{T_e}}\right)$$

The equation for the circuit is

$$e_{x1} + (e_c - e_{x1})\left(1 - \epsilon^{-\frac{t}{T_e}}\right) - i_f r - L\frac{di_f}{dt} = 0 \qquad (10)$$

and its solution is

$$i_f = \frac{e_{x1}}{r} + \frac{e_c - e_{x1}}{r\left(r - \dfrac{L}{T_e}\right)}\left[r - \frac{L}{T_e} - r\epsilon^{-\frac{t}{T_e}} + \frac{L}{T_e}\epsilon^{-\frac{r}{L}t}\right] \qquad (7)$$

Appendix IV. Characteristics of Generator, Exciter, and Regulator

Generator

Rating 40,000 kva, 13,800 volts, 1,670 amperes, single circuit. Tested at 5,800 volts, two circuit, in order to circulate full load current, 3,340 amperes, with 1-ohm impedance per leg.

Reactances under this condition are as follows:

Synchronous reactance, $x_d = 1.92$
Transient reactance, $x_d' = 0.427$
Subtransient reactance, $x_d'' = 0.247$
Field resistance at 40 degrees centigrade $= 0.39$ ohm

Time constants:

Open Circuit $T_{d0} = 10.8$ seconds
Transient $T_{d1}' =$ Full load 5.3 seconds
Half load 6.68 seconds
Subtransient $T_{d1}'' =$ Full load 0.06 second
Half load 0.08 second

Per unit saturation 0.12 at no load, 5,800 volts.

Exciter

Rating 400 kw, 250 volts, shunt wound. Separately excited from 250-volt source. Ceiling voltage with 0.39-ohm load = 334 volts. Nominal voltage for test conditions = 170 volts. $T_e = 0.615$ second (calculated). Nominal response 1.24 (test).

Voltage Regulator

Allis-Chalmers type *J* contact-making rheostatic regulator.

Rating: Control element, 115 volts. Excitation voltage, 250 volts, 100 step bridge-type rheostat with high-speed contactors for sudden load changes.

Discussion

G. W. Staats (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): Rosenberg's paper is doubtless a valuable addition to the existing literature on the phenomenon of voltage dips on generators due to suddenly applied loads, since it treats the problem in a forthright way and the method developed is readily applicable to actual situations. In addition, the equations derived are flexible, so that if it is desired to omit certain factors, for example, subtransient effects, this can be done easily.

The author mentions that the method is believed applicable to loaded machines as well as to static loads applied to an unloaded generator. It should be noted in this connection that the initial loading on a generator has, in general, only a slight effect on the magnitude of the voltage dip produced by a suddenly applied additional load. Figure 1 of the discussion serves to give an example of the effect of various conditions of initial loading, and shows the voltage dips which resulted when 1,500 and 2,000 horsepower motors were started from a 15,625 kva turbine generator of an eastern utility. The solid curves show the generator terminal voltage variation with constant excitation, and the dotted curves show terminal voltage variation when the field current is controlled by a voltage regulator.

Under voltage regulator control, the maximum voltage dip varied from about 11 per cent at no initial load to 9 per cent at full initial generator load when the 1,500-horsepower motor was started. Under the same conditions, the maximum voltage dip varied from 15 to 11 per cent when the 2,000-horsepower motor was started. This small variation over a wide range of initial generator loadings indicates that a method of calculating voltage dips which applies to initially unloaded generators will also apply to initially loaded machines. This conclusion was also reached by Harder and Cheek.[1]

C. Concordia (General Electric Company, Schenectady, N. Y.): The author of this paper refers to a previous analytical treatment in using his equation 5 for exciter voltage, but he prefers to use equation 6 of the paper. We should like to point out that equation 6 has also been used in a previous analysis. In particular, it was used in a paper by W. C. Johnson, Jr., published in 1930.[1] In fact, both equation 6 and equation 5 were used in Johnson's paper. Another analysis, using a linear variation of exciter voltage, was presented by H. C. Anderson, Jr. in 1945.[2]

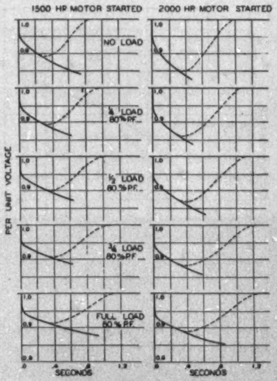

Figure 1. Effect of initial load on voltage dip of a 12.5-megawatt unit

T. B. Montgomery (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): In commenting on this paper I would like to direct my remarks from two points of view:

(A) The engineer applying regulators, of the modern high-speed type, to important generators on a system does not always have the time to do lengthy calculations to show what over-all results the use of such equipment is getting, and, as an application engineer he may not be accustomed to handling calculations involving all the factors, without time-consuming accumulation of data. He seldom has the correct exciter and generator characteristics and load short-circuit time constant conveniently at hand.

The control engineer, therefore, is especially happy to have a method of this type which merely involves the substitution of generator and exciter constants since these values can be obtained readily from the machine designer. Results, which are sufficiently accurate for all practical purposes, may be obtained quickly by those unaccustomed to involved calculations.

(B) From the standpoint of the user, since our standard practice for system stability under fault conditions on feeder and tie-lines remains dependent on clearing by high-speed circuit breakers, what salient advantage do we get from fast response under regulator operation? As recited in previous papers, those systems which, due to added capacity reactance from high-voltage cables as well as from static capacitors on distribution lines, find their excitation values under normal operating conditions lower than ever before and are concerned about the excitation margin above the steady state stability limit. Thus, with low levels of normal excitation (on such systems) immediately following clearing of faults by highspeed circuit breakers, we are concerned with stability between generating units, between stations and busses. We need to know, with as little expense labor as possible, the effect of excitation system response in terms of generating unit flux.

It is generally accepted among users now that response depends on exciter ceiling voltage (this is the primary factor since not much can be done to lower present values of inductance of generator field); on generator short circuit time constant T_{d1}'; exciter time constant T_e; and on regulator time response (this value is negligible on rotating amplifier type regulators).

The method presented is of particular value as a time saver in evaluating the effects of these four factors.

It appears that the success of application of the method depends very greatly on accurate determination of a short circuit time constant T_{d1}' corrected for load and of the exciter time constant T_e.

Since Figures 5 and 6 check fairly close, we would conclude that with high ratio of generator short circuit time constant to exciter time constant (T_{d1}'/T_e) the early part of the transient has an important bearing on the shape of the voltage time curve.

Since it has been customary to figure response under short circuit conditions only, the application of the method is useful especially in predicting the voltage fluctuation as influenced by changes in the control due to sudden load fluctuation. Although not definitely stated in the paper, for other conditions than the sudden short circuiting of the exciter rheostat, the value of T_e will not be related to the nominal exciter response curve as shown in Figure 11 because the build-up of the exciter will be dependent on the control signal that is, it will be proportional to the instantaneous change in output terminal voltage.

Equation 7 might be more conveniently expressed as follows if

$$\frac{L}{r} \text{ is replaced by } T'd,\ i_f = i_{f1} + \frac{(e_c - e_{x1})}{r\left(1 - \dfrac{T'd_1}{T_e}\right)} \times$$

$$\left[\left(1 - \frac{T'd_1}{T_e} - \epsilon^{-\frac{t}{T_e}} + \frac{T'd_1}{T_e}\,\epsilon^{-\frac{(t)}{T'd_1}}\right]$$

in this form it is more easily checked against the curves of Figure 2 of the paper which are given for various values of the ratio $T'd_1/T_e$.

L. T. Rosenberg: The curves presented by Staats cover a wide range in initial load, and yet show very little difference in minimum voltage. The effect of initial load at 80 per cent power factor lagging is shown to actually reduce the voltage disturbance. This is not true however of all types of initial load.

In practice, it is often more important to know the extent of the disturbance when the second motor is being started rather than the first, since with no initial load, there is nothing on the line to disturb. The expressions for the (e_t) values in equations 2 and 4 permit applying the method to two types of initial load.

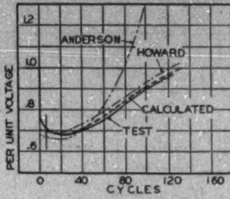

Figure 2. Voltage dip with full load suddenly added

For other types, similar relations may possibly be derived, or interpolation may be employed. As indicated in the paper, the expressions are suitable for removal of load also. If the entire load is removed, it will be noted the two relations, 2 and 4 become identical, as they obviously should.

I wish to thank Concordia for pointing out that equation 6 as well as equation 5 was also assumed for exciter build-up in a previous analysis by W. C. Johnson, Jr., and that a linear relation was used in a later paper by H. C. Anderson, Jr.

The treatment presented by Johnson covering equation 6 was credited to Alan Howard. Both the generator and the exciter voltages are assumed to follow a curve of the form 6 under suddenly increased field voltage. The operational expressions are then found for each circuit, and combined on the basis that the two circuits are linked only by a common electromotive force. The final solution for generator voltage, obtained by means of Heaviside's Expansion Theorem is very similar in form to equation 7 for generator field current.

The voltage components were expressed by Howard in terms of the ratios of external impedance to the total impedance behind synchronous and transient reactances. This limits their application to conditions of no initial load.

In Figure 2 of the discussion, the full-load test of Figure 5 is redrawn together with calculated curves based on both Johnson's and Anderson's papers. As may be expected the linear exciter voltage assumption of Anderson yields results in between those based on equation 5 and equation 6, and hence will only apply over a limited range. Like the other previous papers subtransient effects were not included.

With reference to part *B* of Montgomery's discussion, the value of quick-response excitation on generators and on intermediate synchronous condensers to augment inherent system stability has been recognized for many years, particularly in Europe where generator short circuit ratios of 0.4 to 0.5 are common. It is also well known that application of regulators to some machines on a system will yield more favorable results than to others, and that excessive amplification factors are not always justifiable. To properly evaluate the results of proposed regulating equipment, several alternate schemes must often be studied and compared.

Montgomery refers to Figures 5 and 6, both covering full load, 3-phase tests. Due to a faulty connection, the first test showed several momentary breaks in the exciter field current build-up after about 60 cycles, but the resulting generator voltage rise curves are almost identical. If the major part of the exciter voltage rise occurs in the early part of the disturbance, as it does with a high ratio of T_{d1}'/T_e, the remainder of the generator voltage build-up curve is governed mainly by T_{d1}'. This can be seen readily by reference to Figure 2 of the paper.

The use of Figure 11 to find T_e is confined only to cases where the regulator short circuits series resistance in the exciter field circuit, since nominal response is defined for this condition. Moreover, the curves of Figure 2 of the paper are valid only for exciter voltage build-up which can be approximated by equation 6. For other types of regulators, the actual exciter voltage build-up must therefore be determined, and then either method *B* or *C* of Appendix II may be used to find T_e.

Equation 7 was expressed in terms of *L* and *r* because its derivation is based on constant inductance and resistance of the field circuit.

In applying the curves of Figure 2 for voltage rise, the equation is more useful if expressed in terms of the two time constants T_{d1}' and T_e, as suggested by Montgomery.

The Geometric Loci of the Synchronous Tie

L. A. FINZI

Synopsis: A drive system consisting of two identical polyphase induction machines with their rotors interconnected and with additional secondary impedance networks is analyzed. General families of loci are obtained for the vectors representing the stator currents, and procedures are indicated for the determination of the torques.

TWO INDUCTION machines whose armature windings are supplied with polyphase alternating currents and whose rotors are interconnected, act as a positioning device; a rotation impressed on one of the shafts causes a corresponding motion of the second shaft, as if there were a mechanical coupling of some sort. If both shafts are stationary in arbitrary positions, the voltages induced in corresponding phase windings of the two rotors by the revolving air-gap fields differ in time phase by an angle which depends on the geometrical angle between the two shaft positions, and currents flow in the interconnected rotor circuits so as to generate torques which tend to line up the shafts in an equilibrium position of bucking induced rotor voltages. If both shafts are free to rotate, and if one of them is somehow displaced from such an equilibrium position, the other will follow. If the first is given a continuous rotation, the second also will rotate continuously at the same angular velocity, but with an angular displacement depending on its torque load.

As a remote positioning or indicating device this 2-machine drive falls in the category of the selsyns, while in industrial polyphase applications in which interchanges of considerable power are required, the names "synchronous tie," "synchro-tie," "synchro-lock," "electric shaft," and "power selsyns" are used.

The subject of the synchronous tie has been dealt with in the technical literature both in this country and abroad (See References 1–4). A most general treatment in terms of Kron's tensor analysis has also been developed.[5] The purpose of this paper is to present a steady-state analysis that applies to general drives as represented in Figure 1. The presence of external impedances in the rotor network introduces modifications in the torque–angle characteristics of the tie which may be of practical interest.

The Method of Analysis

In the following, two machines of identical design and size are considered, together with an additional rotor circuit network of balanced impedances which is reducible to a symmetrical *T*. The impressed stator voltages are of equal amplitude and frequency. These restrictions actually are not essential for a synchronous operation of the tie, since the only condition required for the existence of synchronizing torques is the equality of the frequencies of the induced rotor voltages. The restrictions are made chiefly in order to simplify the procedures and the form of the results.

The method of analysis is to establish an equivalent circuit, with the general procedures and assumptions which are customarily used in the circuit analysis of the induction machine. The currents in the various branches are obtained then by applying Kirchhoff's laws, and are functions of the two independent variables, per unit slip s, and relative phase angle δ, in electrical radians, of the two induced rotor voltages. Families of loci of the current vectors are derived, and, from these, torques and electrical and mechanical powers are evaluated for any steady-state operating condition.

It may be noted that names such as "transmitter" and "receiver," commonly used for selsyns, lead to confusion in this general case since they imply a definite flow of power from one shaft to the other while actual operating conditions are possible in which both shafts deliver (or absorb) mechanical power. It appears preferable, therefore, to distinguish between the two machines by means of the time phase of the induced rotor voltages. Thus, the machine of the synchronous tie whose induced rotor voltages lead in time the corresponding voltages of the other machine by a positive phase angle δ (ranging between zero and π) is called the "leader"; the other is called the "lagger." When the shafts rotate in directions opposite to those of their respective air-gap fields (that is, for slips greater than one), or when they rotate in the same directions as the fields but at a higher angular velocity (that is, for negative slips), the machine designated as leader, according to the definition above, is the one whose shaft leads that of the other in the direction of mechanical rotation. On the other hand, when the shafts rotate with the fields, but at a lower speed (that is for slips ranging between zero and one) the leader is the machine whose shaft is lagging in the direction of mechanical motion.

Figure 2(*a*) represents a single-phase equivalent circuit of the synchronous tie, with all secondary quantities reduced to primary terms. The subscripts *a* and *b* distinguish the two machines; 1, 2, and 0 refer to the stator, rotor, and exciting branches respectively, α and γ are used

---

Paper 49-51, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 15, 1948; made available for printing January 4, 1949.

Wellard, at present with the International Resistance Company, Philadelphia, Pa., was formerly a graduate student with Carnegie Institute of Technology and some of this paper was presented in partial fulfillment of the requirements for the degree of Master of Science.

The authors acknowledge the helpful criticisms of their associate, H. M. McConnell.

for the circuit parameters representing the external network, V is the line-to-neutral voltage. The phase angle existing between induced rotor voltages is introduced in the equivalent circuit by means of an ideal phase-shifter, *Ph*, with ratio of transformation 1:1.[6] According to the convention established, the machine *b* in Figure 2(*a*) is the leader.

Figure 2(*b*) shows a modified equivalent circuit in which the ideal phase-shifter has been transferred to the stator terminals of machine *b*. It is easy to verify that the use of either equivalent circuit leads to the same expressions for all branch currents designated with the same symbols in both figures.

In any case I_{a1} and I_{b1} are the line currents at the terminals of the two stators, while the current of slip frequency which actually flows into the shunt branch of the external impedance network has the value

$$I_\gamma = I_{a2} + I_{b2}\,\epsilon^{j\delta} \qquad (1)$$

(reduced to primary terms).

The Vectorial Loci of the Stator Currents for δ Constant and Variable s, (s-loci)

These loci are obtained in parametric form in equations 20 and 21 in the Appendix. For the simple synchronous tie without external networks (or also for the more general case in which an external network is added whose α branches consist of a resistor and an inductance in series and whose γ branch has only inductance), these equations simplify to

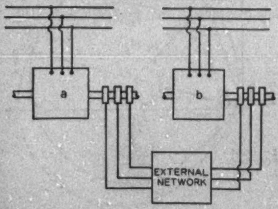
$$I_{a1} = V\frac{A+A's}{D+D's} \qquad (2)$$

and

$$I_{b1} = V\frac{B+B's}{D+D's} \qquad (3)$$

Thus the s-loci are circles whose centers and radii are obtained easily.

Figure 1. Synchronous tie with external impedances



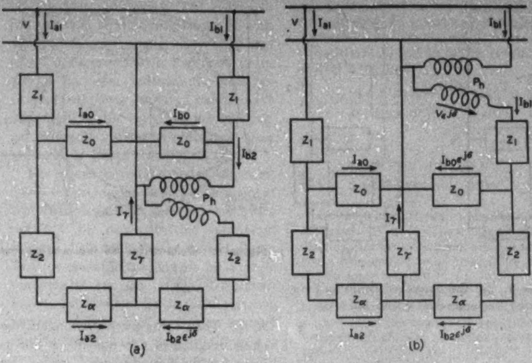


Figure 2. Equivalent circuits of the synchronous tie

$Z_0 = R_0 + jX_0$ $\qquad$ $Z_1 = R_1 + jX_1$

$$Z_2 = \frac{R_2}{s} \times jX_2$$

Z_α and Z_γ are functions of s

If, however, the γ-branch has resistance (that is $Z_\gamma = R_\gamma/s$ or $Z_\gamma = R_\gamma/s + jX_L$) equations 20 and 21 become

$$I_{a1} = V\frac{A+A's+A''s^2}{D+D's+D''s^2} \qquad (4)$$

and

$$I_{b1} = V\frac{B+B's+B''s^2}{D+D's+D''s^2} \qquad (5)$$

Thus the s-loci are bicircular quartics. These curves of the fourth order have a number of remarkable properties which may facilitate to some extent their construction by analytical or projective geometry procedures.[7]

If, as a further example, the external network consists of shunt capacitors (that is $Z_\alpha = 0$, $Z_\gamma = -jX_c/s^2$), the numerators and denominator of equations 20 and 21 and become polynomials of the fourth degree in s; this is the s-loci which are curves of the eighth order.

The Loci of the Stator Currents for s Constant and Variable δ (Delta-circles)

More convenient expressions for the stator currents are offered by

$$I_{a1} = V(H + K\epsilon^{j\delta}) \qquad (6)$$

and

$$I_{b1} = V(H + K\epsilon^{-j\delta}) \qquad (7)$$

For constant slip and variable δ, the loci of the current vectors are circles whose center and radius are obtainable from equations 15 through 19. A quicker determination of these delta-circles for any value of s is possible, however, if two s-loci are already known.

It is convenient to choose as basic s-loci for the construction of the delta-circles, the s-loci of I_{a1} for $\delta = \pi$ and $\delta = 0$. For these values of the phase angle, $I_{a1} = I_{b1}$, and, in view of the existing symmetry, the equivalent circuit simplifies to the circuits of Figures 3(*a*) and 3(*b*) respectively.

For $\delta = \pi$, no current flows in the γ-branch. If, in particular, $Z_\alpha = 0$, this locus coincides with the conventional circle diagram of one machine, and can be determined, from design or test data with any one of the various familiar procedures.

For $\delta = 0$, and no external networks (that is, $Z_\alpha = 0$, $Z_\gamma = \infty$), the s-locus shrinks to the tip of the vector representing the no-load current of a single machine. Hence the various delta-circles constitute a pencil of curves through this singular point. In the case of a simply-resistive shunt, the s-locus for $\delta = 0$ is again the circle diagram of a single machine, although with a different slip scale; while in the case of a simply-capacitive shunt, this locus becomes a bicircular quartic, whose determination, however, is still reasonably easy by means of the circuit of Figure 3(*b*).

In any event, for any conceivable type of external network, the s-loci for $\delta = 0$ and $\delta = \pi$ are easily obtained experimentally, within the range of speeds of practical

interest, by simple tests performed on a single machine whose slip rings are connected to conveniently chosen external impedances.

The further use of these two particular s-loci for the general determination of the currents I_{a1} and I_{b1}, for any speed and angular displacement of the shafts, by means of constructed delta-circles is illustrated in Figures 4, 5, and 6.

Figure 4 refers to a simple synchronous tie without external network ($Z_\alpha=0$, $Z_\gamma=\infty$). As mentioned before, the s-locus for $\delta=\pi$ coincides with the circle diagram of one of the machines, while the s-locus for $\delta=0$ shrinks to the tip of the vector representing the no-load current. The constructions indicated with full lines lead to the determination of both stator currents for slip = 0.5, and for a relative rotor displacement of 60 electrical degrees. Also indicated, with dash-dot lines, are the vectors of the two stator currents for $s=1.4$ and for the same rotor angle, $\delta=60$ degrees. In either case, machine b is the leader in terms of induced rotor voltages, and absorbs electric power from the line, while machine a returns power to the line. For $s=1.4$ (this is rotation against the air-gap field), rotor b is also leading in terms of mechanical rotation; for $s=0.5$ (rotation with the field), rotor b, however, is lagging mechanically. Figure 4 applies to a set of two 10-horsepower 1,120-rpm 60-cycle 3-phase induction motors with the following per-unit impedances

$R_0=0.26$, $X_0=2.14$
$R_1=0.033$, $X_1=0.124$
$R_2=0.05$, $X_2=0.124$

(Unity current is defined as rated mechanical output per phase divided by rated stator voltage per phase.)

Figure 5 refers to the same tie with an additional shunt resistance ($Z_\alpha=0$, $Z_\gamma=R/s$). The s-locus for $\delta=\pi$ is again the circle diagram of one machine. The s-locus for $\delta=0$ is the same circle; its different slip scale is also indicated in Figure 5, in which it is assumed that $R_\gamma=0.10$. Constructions for $s=0.5$ and $\delta=60$ degrees are given. It may be noticed that for these values of the two independent variables, both machines absorb power from the line. As a matter of general interest, portions of the fourth order loci of I_{a1} and I_{b1} for $\delta=60$ degrees and variable slips, as obtainable from repeated constructions of delta-circles, also have been plotted in Figure 5.

Figure 4. Delta-circles of the synchronous tie, $Z_\alpha=0$, $Z_\gamma=\infty$

Finally, Figure 6 refers to the tie with an additional shunt capacitance ($Z_\alpha=0$, $Z_\gamma=-jX_c/s^2$). Once more the s-locus for $\delta=\pi$ coincides with the circle diagram of one machine. A portion of the bicircular quartic, which is the s-locus for $\delta=0$, has been calculated numerically for a few values of s, assuming $X_c=3.62$ per unit. Constructions for I_{a1} and I_{b1} are indicated for $s=1.5$ and $\delta=60$ degrees.

The Torque Axes

Powers and torques for either machine of the tie can be obtained from the knowledge of I_{a1} and I_{b1} by means of customary procedures. A quick way for evaluating torque-angle characteristics at constant speed, however, is offered by the particular nature of the delta-loci. For this purpose the approximation is accepted that the power transmitted to the rotor of either machine by its revolving field, that is, the torque in synchronous watts, is expressed by:

air gap power = electric input − stator I^2R losses − no-load core losses

The torque is positive if acting upon the rotor in the direction of the revolving air-gap field. Whenever the locus of the stator current is a circle, it is possible to determine a straight line such that the distance between the tip of the vector representing the stator current and this line is proportional to the difference (power input—stator I^2R losses). The proof of this statement, as given in text books with particular reference to the circle diagram of the conventional induction motor,[8] is in fact valid quite generally, and applies to the delta-circles of the synchronous tie as well. The coefficients of the equation of this straight line depend on the coordinates of the center of the locus and on its radius. For the delta-circle of the stator currents $I_1=H+K\epsilon^{\pm j\delta}$, in a cartesian system of co-ordinates in which $H=y_h-jx_h$, the slope of the line is

$$\frac{dy}{dx}=\frac{x_h}{(V/2R_1-y_h)} \tag{8}$$

its intersection with the y-axis is

$$y_0'=-1/2\,\frac{x_h^2+y_h^2-K^2}{V_1/2R_1-y_h} \tag{9}$$

and

$$\text{(power input}-I^2R\text{ losses)}=m(V-2y_hR_1)\times d'$$

where m is the number of stator phases and d', read in the scale of the currents, is the distance between the tip of the

——— $Z_\gamma = \frac{R_\gamma}{s}$

current vector and this straight line, measured in the direction of the y-axis.

The air-gap power is obtained by further subtraction of the no-load core losses; thus the torque axis for the delta-circle in question results from a convenient parallel translation of the previous straight line in the y-direction, its intercept with the y-axis being

$$y_0 = y_0' + \frac{\text{no-load core loss}}{m} \times \frac{1}{V-2y_hR_1} \quad (10)$$

Hence air-gap power $= m(V-2\,y_h\,R_1)\,d$ where d is the distance between vector tip and torque axis, measured in y-direction.

Figure 5 indicates the construction of the torque axis for the delta-circle at $s=0.5$ for the case of the synchronous tie with external shunt resistance. It appears, from the position of this circle with respect to the co-ordinate axes, that the term $2\,y_h\,R_1$ may not be neglected in calculating the torque scale factor, as it may be practiced sometimes in simplified manipulations on the circle diagram of conventional induction motors.

Figure 7 shows plots of torque–angle characteristics for $s=0.5$; the dotted lines refer to the simple synchronous tie without external impedances, as obtained also by previous authors.[3,4] The curves in full line refer to the synchronous tie with external shunt resistance $R_\gamma=0.10$ analyzed in Figure 5. In Figure 7, unity torque has been chosen as the ratio between rated power output of one machine and rated motor speed; leader and lagger are defined in terms of induced rotor voltages, as stated initially.

The procedures established so far permit quick determination of the performance of the synchronous tie with external rotor networks for any operating speed and relative shaft angle, on the basis of design data or of simple tests made on a single machine of the set. In a subsequent paper, in preparation, these general methods will be used to discuss in more specific terms design considerations for a number of typical applications.

Appendix

For the equivalent circuit of Figure 3 the following loop equations are written

$$V = Z_1I_{a1} + Z_0(I_{a1} - I_{a2}) \quad (11)$$

$$V = Z_1 + I_{a1}(Z_2 + Z_\alpha)I_{a2} + Z_\gamma(I_{a2} + I_{b2}\epsilon^{j\delta}) \quad (12)$$

$$V\epsilon^{j\delta} = Z_1I_{b1}\epsilon^{j\delta} + Z_0(I_{b1}\epsilon^{j\delta} - I_{b2}\epsilon^{j\delta}) \quad (13)$$

$$V\epsilon^{j\delta} = Z_1I_{b1}\epsilon^{j\delta} + (Z_2 + Z_\alpha)I_{b2}\epsilon^{j\delta} + Z_\gamma(I_{b2}\epsilon^{j\delta} + I_{a2}) \quad (14)$$

Solving for I_{a1} and I_{b1}

$$I_{a1} = V\frac{N_a}{\Delta} \quad (15)$$

and

$$I_{b1} = V\frac{N_b}{\Delta} \quad (16)$$

with

$$N_a = [(Z_1+Z_0)(Z_2+Z_\alpha+Z_\gamma)+Z_1Z_1](Z_0+Z_2+Z_\alpha+Z_\gamma) - Z_\gamma^2(Z_1+Z_0) - Z_0^2Z_\gamma\epsilon^{j\delta} \quad (17)$$

$$N_b = [(Z_1+Z_0)(Z_2+Z_\alpha+Z_\gamma)+Z_1Z_0](Z_0+Z_2+Z_\alpha+Z_\gamma) - Z_\gamma^2(Z_1+Z_0) - Z_0^2Z_\gamma\epsilon^{j\delta} \quad (18)$$

and

$$\Delta = [(Z_1+Z_0)(Z_2+Z_\alpha+Z_\gamma)+Z_1Z_0]^2 - Z_\gamma^2(Z_1+Z_0)^2 \quad (19)$$

where Z_2, Z_α, and Z_γ are functions of the slip s. (It will be remembered, in fact, that, if the secondary network has resistors R and inductors and capacitors respectively of reactance X_L and X_c at line frequency, these elements shall be introduced in the equivalent circuit as R/s, X_L, and X_c/s^2.)

Equations 15 and 16 can be rewritten in general in the form

$$I_{a1} = V\,\frac{A+A's+A''s^2+\ldots+A^ns^n}{D+D's+D''s^2+\ldots+D^ns^n} \quad (20)$$

and

$$I_{b1} = V\,\frac{B+B's+B''s^2+\ldots+B^ns^n}{D+D's+D''s^2+\ldots+D^ns^n} \quad (21)$$

where the D are constant, while the A and B are functions of δ. Thus numerators and denominator are polynomials in s of nth degree, n depending upon the nature of the chosen rotor network.

For constant δ, 20 and 21 are parametric equations of the loci of the current vectors I_{a1} and I_{b1} in the complex plane, these loci being curves of order $2n$ (called s-loci in this paper).

Equations 15 and 16 can also be rewritten in the form

$$I_{a1} = V(H + K\epsilon^{j\delta}) \quad (6)$$

$$I_{b1} = V(H + K\epsilon^{-j\delta}) \quad (7)$$

where H and K are functions of s, seen by inspection of equations 17, 18, and 19.

Thus, for constant s and variable δ, the loci of the current vectors I_{a1} and I_{b1} become circles (called delta-circles in this paper).

Voltage-Recovery Characteristics of Distribution Systems

R. L. WITZKE
MEMBER AIEE

THE performance of distribution-system protective devices, such as expulsion-type lightning arresters, fuses, reclosers, and so forth, is influenced by the voltage-recovery characteristics of the system on which they are applied. Successful operation of a protective device requires proper co-ordination between the apparatus dielectric-recovery characteristics and the system voltage-recovery characteristics. The adequacy of the device is checked by employing laboratory test circuits having recovery voltages at least as severe as those experienced in practice on actual systems. The study reported in this paper was made to obtain the necessary fundamental data for predicting the most probable voltage-recovery characteristics of distribution circuits in the 2,400-to-13,800-volt classes. Previous papers[1,2,3] gave similar data for systems operating at the higher voltages, however, the results of these studies are not applicable generally to the lower-voltage systems because of the differences in source reactances, line lengths and conductor spacings. Furthermore, the development of procedures for estimating the characteristics of distribution systems, having a multiplicity of trunk lines, radial laterals, and so forth, was required.

A general study was made on the analog computer for a 4-wire multigrounded system, over a wide range of source reactances, line lengths and conductor sizes. Consideration was given to single- and double-line-to-ground faults and to fault location.

The final data give times to 90 per cent voltage and to the maximum recovery voltage as a function of source reactance and line length. Data on the maximum recovery voltage on these systems, for both single- and double-line-to-ground faults, also are included. Although the general study was made on the basis of a source and a single overhead circuit, methods are included for estimating the voltage-recovery characteristics of the more complicated, practical systems.

Additional studies were made for 3-phase, 3-wire and for single-phase systems to compare the characteristics of these systems with the corresponding characteristics of 4-wire systems. The effects of methods of system grounding, short sections of cable and fault resistance also were investigated.

List of Symbols

E_m = maximum recovery voltage in per cent of normal line-to-ground crest voltage
T_m = time to maximum recovery voltage in microseconds
$T_{0.9}$ = time to 90 per cent voltage, where 100 per cent is normal line-to-ground crest voltage
X = positive-sequence source reactance in ohms at 60-cycles
M = connected line in miles per phase

Summary and Conclusions

Previous studies,[1,2,3] and a review of protective device dielectric-recovery characteristics, showed that the significant points on a system recovery-voltage curve could be defined with practical accuracy by the following data:

1. The time required for the system voltage to recover to 90 per cent of normal line-to-ground voltage.
2. The magnitude of the maximum voltage, expressed in per cent of the normal line-to-ground crest voltage.
3. The time required for the system voltage to reach the maximum value obtained.

Theoretical considerations and analog computer studies showed that the X/M ratio of a distribution system, where X is the 60-cycle source reactance in ohms and M is the miles of connected line per phase, may be used as the fundamental variable in recovery-voltage studies, whenever the system natural frequencies are high by comparison to the fundamental system frequency, and losses are not a significant factor in determining the voltage-recovery characteristics. The natural frequencies of all solidly-grounded systems studied were high by comparison to 60 cycles, and losses had only secondary effects, even with number 6 conductors. This conclusion allowed expressing all significant data for solidly-grounded systems as a function of the X/M ratio, and greatly increased the possible scope of the studies, see Figures 7 and 8.

A general study was made for a 4-wire system, consisting of a solidly-grounded source and a single overhead circuit of average conductor configuration, for X/M ratios between 0.0625 and 8.0. Fault location was found to have an important influence on the data, so four fault locations were considered in each study, and the data giving the most severe recovery characteristics were used. Fault location was then eliminated in the final summaries on the basis that protective devices must be applicable to any location on a circuit. The times to 90 per cent voltage and to maximum voltage, divided by the line length in miles, were plotted as a function of the X/M ratio. Even though both single- and double-line-to-ground faults, and 4/0 and number 6 conductors were considered, the resulting times for a given X/M ratio did not vary more than 30 per cent from the minimum times obtained. In most cases the mini-

(A) Circuit
(B) Voltage and current relations
(C) Comparison of system recovery-voltage with expulsion-type lightning arrester dielectric characteristics, T_1 and T_2

mum times were at least 80 per cent of the maximum times recorded.

The maximum voltages obtained with 4/0 conductors (approximately 175 per cent for a single line-to-ground fault and 205 per cent for a double-line-to-ground) did not vary appreciably with the X/M ratio. With number 6 conductors, these voltages varied between 125 per cent at low X/M ratios, and the 4/0 conductor values at high X/M ratios. The main influence of conductor size was to change the phase angle of the fault path.

These results indicate one practical approach to the distribution-system recovery-voltage problem, and that is to eliminate conductor size as a variable, and use the same times to 90 per cent and maximum voltage for single- and double-line-to-ground faults.

A study of solidly-grounded systems with parallel circuits on the same bus led to conclusions, as follows:

1. The times to maximum recovery voltage decreased as the number of parallel circuits was increased, assuming the same total miles of connected line. These times could be estimated, for the limiting case of an infinite number of parallel circuits, by the simple relation

$$T_m = 15.9\sqrt{XM} \text{ microseconds}$$

2. The times to 90 per cent voltage could be estimated by one of the relations

$$T_{0.9} = 13.8\ NX \text{ microseconds}$$

or

$$T_{0.9} = 7.7\sqrt{XM} \text{ microseconds}$$

depending upon which gives the minimum time.

In the foregoing relations X is the 60-cycle source reactance in ohms, N the number of parallel feeders connected to the supply bus, and M the connected line, in miles per phase, including trunk feeders and laterals.

Special studies showed that the 4-wire system data could be applied to 3-wire and single-phase, solidly grounded systems. Reactance or resistance grounding decreases the severity of the recovery-voltage transients following single-line-to-ground faults, but increases the maximum voltages following double-line-to-ground faults.

Theory

The simple circuit in Figure 1(A) will be used to define system recovery voltage and to illustrate its influence on the performance of protective devices. In this circuit the power source is represented by a voltage and an inductance, and the line by a capacitance. Applying a short circuit across the capacitor is equivalent to applying a fault on a single-phase system. The fault current will lag the internal voltage of the source by 90 degrees as shown in Figure 1(A) because resistance has been neglected. When the fault is removed, at the instant the fault current passes through zero, the voltage across the capacitor returns to normal after a series of oscillations. The volt-time curve, measured across the capacitor following the removal of the fault, is referred to as the recovery-voltage of the circuit because it defines the manner in which the circuit voltage "recovers" after the fault is removed. This voltage will reach a maximum value equal to twice normal crest circuit voltage if losses are neglected. Losses will limit the maximum voltage to less than 200 per cent, and will damp out the oscillation after a number of cycles. The time to maximum recovery-voltage is equal to $\pi\sqrt{LC}$ for the simple circuit used in the illustration. As L depends on the source reactance and C is proportional to line length, the times associated with the voltage recovery characteristics of a system are a function of source reactance and line length.

The recovery-voltage curve of Figure 1(B) is replotted in Figure 1(C) with an expanded time scale. Also included are dielectric-recovery curves for two expulsion-type lightning arresters. The latter curves define the voltage that a lightning arrester can withstand at various time intervals after the lightning arrester ceases to conduct fault current. It will be remembered that a lightning arrester is a good conductor during the discharge and power-follow periods, and then must become a good insulator after the fault current is interrupted by the lightning arrester. This change from a conductor to an insulator does not take place instantly, but occurs gradually as indicated by the dielectric-recovery curves. For satisfactory performance, the lightning arrester characteristic curve must lie above the system recovery-voltage curve. Lightning arrester T_1 would restrike at point A, Figure 1(C), whereas lightning arrester T_2 would withstand the recovery voltage without restriking. Similar coordination between device and system characteristics is required for satisfactory performance of other protective devices such as fuses, reclosers, and so forth.

The voltage-recovery curve for a typical distribution system, shown in Figure 2(A), differs from the curve for the simple circuit of Figure 1(A) only in that it contains more than one natural frequency, and consequently is not a simple sine-wave function. Experience has

shown that only two significant points on the recovery-voltage curve are required to obtain co-ordination with protective-device characteristics. These are the time to 90 per cent voltage, and the time and magnitude associated with the maximum value of the recovery-voltage. These significant points, connected by a straight line, are compared with an expulsion-type lightning arrester characteristic curve in Figure 2(B).

Distribution Systems. The wide variety of systems in current use, and the range in circuit constants encountered, made it impractical to make general studies for all types of systems. For this reason, the more popular system, consisting of 4-wire multigrounded neutral primaries and a solidly grounded source, was investigated in detail.

Special studies then compared this system with the other systems in common use, insofar as recovery-voltage characteristics are concerned. This procedure has proved to be satisfactory because the significant characteristics do not vary greatly with the type of system considered. The grounding of the source was found to be an important factor, and was the basis of additional special studies.

The Analog Computer. Most of the studies reported were made on the analog computer;[4] a few special cases were calculated. The computer is essentially the same as the network calculator used in the 1938 recovery-voltage study; differing primarily in the number and characteristics of the circuit elements and voltage sources. The system studied is represented in miniature by means of inductors, capacitors, and resistors. Low-impedance 3-phase 60-cycle sources are available for representation of the fundamental-frequency system voltages. Faults are applied and removed with special synchronous switches to simulate the operation of protective devices. The transient being studied is repeated ten times per second and appears on a cathode-ray oscilloscope as a steady-state wave. Studies similar to the ones reported in this paper would be classified as impractical without an analog computer, or its equivalent.

The system selected for study and its equivalent circuit are illustrated in Figure 3. The system consists of a delta-star transformer bank, solidly grounded on the star side, and connected to an infinite bus on the delta side. The neutral wire of the single, 4-wire primary is assumed to be multigrounded. The impedance of the transformer supply is represented by three reactors in the 3-phase equivalent circuit. The line is represented by π sections, the actual number being determined by the source reactance and the length of the primary circuit. As many as eight π sections, requiring 68 circuit elements, were used in the general studies. The synchronous switches, representing ground faults, can be switched to any point in the equivalent line section by dial switches. In recovery-voltage studies a cathode-ray oscilloscope is connected to measure the voltage directly across the synchronous switches.

General Study

The important variables considered in the general 4-wire system study are as follows: source reactance; line length; conductor size; fault location; and type of fault, both single-line-to-ground and double-line-to-ground.

The positive-to-zero sequence reactance ratio of the source was made equal to one, corresponding to the assumption that all of the source reactance was in a solidly-grounded, delta-star transformer bank. The resistance of the source was represented by the inherent losses of the reactors used to represent the source reactance. The reactance-to-resistance ratio of these reactors was always higher than the probable ratio for distribution or power transformers, over the entire range of frequencies encountered in the study. Sixty-cycle source reactance of 2, 4, 8, 16, and 32 ohms, and line lengths of 2, 4, 8, 16, and 32 miles were considered. Data for systems outside of these ranges can be estimated from the data obtained.

Geometric-mean distances of 2.66 feet between phase conductors, and 4.1 feet between the phase and the neutral conductors were assumed. These spacings give reactances that are an average of the values obtained over the range of spac-

ings normally used between 2,400 and 13,800 volts. The small variations introduced by changes in spacing were not considered significant in the general problem. A conductor height of 30 feet and a ground resistivity of 100-meter ohms were used in all studies. The phase and neutral-conductor sizes were assumed to be the same, and were varied between 4/0 and number 6 copper. The line constants for these two extreme conductor sizes are included in Table I.

Fault location was found to have a significant effect so was retained as a variable. Previous studies[1,2] considered only one fault location, which was permissible because the circuits were grounded at both ends of the line section. In the present study, with only one ground point, the fault location could not be neglected. Faults were applied on the sending end bus and at the 1/4, 1/2 and 1.0 points, the latter being the open end of the line. Data were obtained for both single- and double-line-to-ground faults.

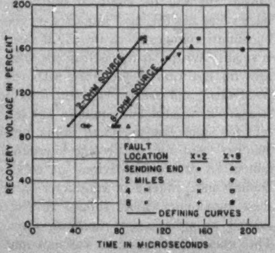

Figure 6. Method of recording and interpreting data illustrated for a single-line-to-ground fault on 8-mile, 4-wire system

Method of Study. The large number of conditions selected for study (five source reactances, five line lengths, four fault locations and two types of faults—a total of 200 cases) made it desirable to simplify and generalize the procedure as much as possible without introducing important errors. It was realized that two systems having the same X/M ratio (ratio of source reactance in ohms to line lengths in miles) would have the same recovery voltage curves, excepting for a difference in time scale. For example, the recovery voltage curve for a 4-ohm 4-mile system has the same shape as the curve for an 8-ohm 8-mile system. The times associated with the 8-mile case would be twice those for the 4-mile system. With this in mind, the X/M ratio was adopted as the fundamental variable in the general study. It was found that if data were obtained for X/M ratios between 0.0625 and 8.0, data for systems falling outside of these limits could be obtained with satisfactory accuracy by extrapolation. This procedure reduced the original 200 cases to the 64 actually studied on the computer. Eight systems, having different source reactances and line lengths, were selected to give the desired X/M ratios.

It should be noted that the foregoing procedure is permissible only when the natural frequencies of the systems considered are high by comparison to the fundamental system frequency, and when high-frequency losses are not too significant in the solution. The lowest natural frequencies of the selected systems ranged between approximately 600 and 18,000 cycles. The reactance-to-resistance ratios for overhead lines increase with frequency, and are reasonably large in the important frequency range, even with number 6 copper. As this ratio is a measure of decrement (a ratio of ten introduces a decrement factor of 0.85 per half cycle of a free oscillation), it was concluded that high-frequency losses were not particularly important in the study.

Some weight was given to high-frequency losses by leaving the faults on until most, if not all, of the initiating transients were damped out. This procedure is justified because of the high frequencies involved during single- or double-line-to-ground faults. For example, a 16-mile 8-ohm system has natural frequencies of at least 2,000 cycles during single-line-to-ground faults. Assuming the fault is applied at near crest line-to-neutral voltage, more than 33 half-cycles of the transient oscillation will elapse, before the fault is removed at the first current zero, which occurs after one half-cycle of the fundamental frequency. Giving some weight to the high-frequency losses of the source, this oscillation would be reduced to negligible proportions by the time the fault is removed. This conclusion was reached by assuming a source damping factor of 0.85 per half-cycle of the high-frequency oscillation. This

(b) 2 L-G FAULTS

Figure 8. Maximum recovery voltages as a function of *X/M* ratio

value has been proposed[5] as being typical for terminal equipment and appears to be within reason for the transformer sources considered in this study.

The initiating transient may have some small effect on the voltage-recovery characteristics of the 32-mile lines studied, especially with the larger source reactances. This, however, is not of practical importance because distribution systems having this much line would have a multiplicity of trunk feeders and laterals, which tend to decrease the magnitude of the recovery-voltage transients.

Previous studies[1,2] considered the effect of varying the point on the 60-cycle voltage wave where the fault is applied. This complication was not required in the present study because the instant of fault application is important only in those cases where the initiating transient has appreciable influence on the recovery-voltage transient.

It was found that the 60-cycle reactance-to-resistance ratios were important, and these were represented correctly, even where time-base multipliers were introduced to keep the system natural frequencies within the preferred frequency range of the Computer.

Results of General Study. The general studies were made by applying single- and double-line-to-ground faults at four locations, and recording the times to 90 per cent voltage, and the times and magnitudes associated with the maximum recovery-voltage transient. These data are illustrated in Figure 6 for the case of a single-line-to-ground fault on an 8-mile system. Time is expressed in microseconds and voltage in per cent of normal line-to-ground crest voltage. It is evident that fault location has considerable influence on the pertinent data. With a 2-ohm source, the time to 90 per cent voltage is a minimum for a sending-end fault, whereas a receiving-end fault dictates this time with an 8-ohm source. It will also be observed that the maximum voltages are obtained for faults away from the sending-end bus. However, many cases were noted where the maximum voltage did occur for sending end faults, especially where small line conductors were represented. This illustrates the complexity of the problem, and the need for considerable data before formulating conclusions.

As it would be impractical to summarize, in the form of useful curves, all of the data obtained, simple uniform method of interpretation was adopted. As a protective device must function at any location on a circuit, it is necessary to know only the most severe circuit conditions, regardless of fault location. With this in mind, a straight line was drawn to connect the points giving the minimum times to 90 per cent and maximum recovery voltage. This line then defines the voltage-recovery characteristics of the particular system. In certain cases, such as the 8-ohm system in Figure 6, the defining straight line was extended through one maximum voltage point to a horizontal line that intercepts the highest voltage recorded. This results in a simple method of plotting data without being ultra conservative. In the case illustrated, the maximum recovery voltage would be recorded as 170 per cent at 140 microseconds.

The times to 90 per cent and to maximum recovery voltage were obtained by plots similar to Figure 6. These times were then reduced to a 1-mile basis by dividing by the line length in miles; then plotted as a function of the *X/M* ratio (ratio of source ohms to line length in miles.) These data are summarized in Figure 7 for single- and double-line-to-ground faults, and 4/0 and number 6 copper conductors. It will be observed that the times, for a given *X/M* ratio, do not vary greatly with the type of fault or the conductor size, even though consideration has been given to various fault locations. For this reason, it was decided that practical answers could be obtained by drawing a single curve under each set of data. The differences between the actual times and those defined by the lower-limit curves were not considered important in view of the complexity of the over-all problem, and the complicated circuits encountered in practice.

The actual times for any given line length can be obtained by multiplying the values in Figure 7 by the line length in miles. Data obtained in this manner are plotted in Figure 9 for a range of source reactances and line lengths.

The maximum voltages measured are plotted in Figure 8 as a function of the *X/M* ratio. Values are included for four conductor sizes, which allows an evaluation of this variable on the voltages obtained. It will be observed that conductor size has the most influence on the maximum voltages when the *X/M* ratio is small. With 4/0 conductors the voltages do not vary appreciably with the *X/M* ratio, and can be represented by a straight horizontal line equal to 175 per cent for single-line-to-ground faults, and 205 per cent for double-line-to-ground faults. If protective devices are to be applied independent of conductor size, these maximum values should be considered as a basis for standardization. The maximum recovery voltages are plotted in Figure 10 as a function of source reactance in ohms and line length in miles. The voltages are expressed in per cent of

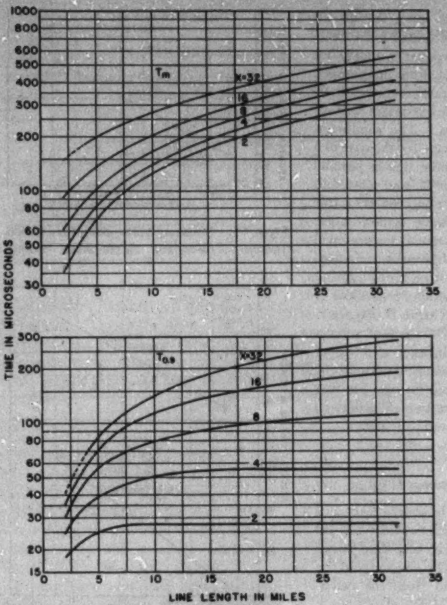

Figure 9. Times to 90 per cent and maximum recovery voltage for a system consisting of a solidly-grounded source and a single overhead circuit

normal line-to-ground crest voltage, and apply to systems in the 2,400-to-13,800-volt range.

Special Studies

A number of special studies were made to show the influence of a number of factors not included in the general study. The data in Figure 11 were obtained for a 3-wire system having the same equivalent phase conductor spacing as used in the 4-wire system study. The results are compared with the general curve data, Figures 9 and 10, to show the relative severity of the recovery-voltage transients on the 3-wire and 4-wire systems. These results indicate that satisfactory performance of protective devices would be obtained on solidly-grounded 3-wire systems, if designed to meet the conditions imposed by a 4-wire system.

Single-Phase System. Figure 12 summarizes the data obtained for a single-phase, multigrounded neutral system having a conductor spacing equal to the equivalent phase conductor to neutral conductor spacing of the 4-wire system. The comparison between these results and the single-line-to-ground fault data for the 4-wire system indicates that the general study results can be applied to single-phase systems with safety.

Unigrounded, 4-wire System. Although the unigrounded, 4-wire system was not studied on the computer, the recovery-voltage characteristics of this system should be no more severe than those for a 3-wire system. The data for this type of system can therefore be estimated with practical accuracy from Figures 9 and 10.

Effect of Load. Load will usually have a damping action on recovery-voltage transients, and so should introduce some margin in the results reported in this paper. The load on distribution systems may be quite small during light-load periods so should not be depended upon to limit transient voltages. One study made with an 80 per cent power-factor load equal to 20 per cent of the supply transformer rating did not show any important differences, with and without load.

Cable Terminations. Many overhead lines leave the substation through short sections of cable. Studies were made with 200-, 400- and 800-foot cables having a capacitance of 0.1 microfarad per 1,000 feet. These results, for a 16-mile line, are plotted in Figure 13, and indicate only minor differences as compared to the general study data.

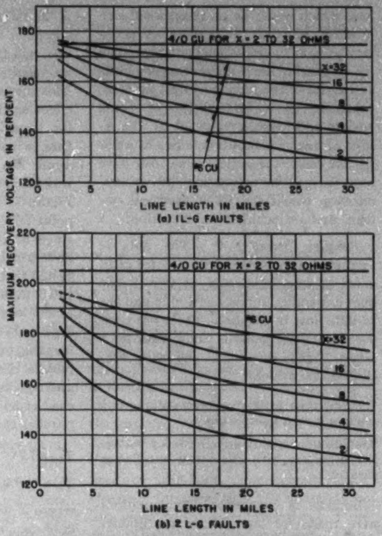

Figure 10. Maximum recovery voltages for a system consisting of a solidly-grounded source and a single overhead circuit

General Circuit Arrangements

The general curves, Figures 7 to 10, were obtained for a source and a single

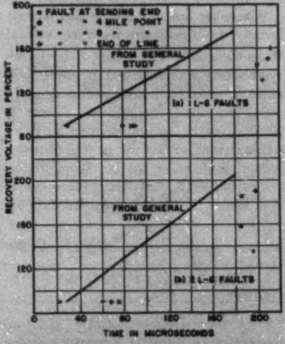

Figure 11. Recovery-voltage data for a 2-ohm 16-mile 4/0-copper solidly-grounded 3-wire system

line, which would be an exceptional condition in practice. It is therefore necessary to have available a definite procedure for estimating the voltage-recovery characteristics of the more practical systems, consisting of a multiplicity of trunk feeders and laterals. Guided by the results of analog computer studies of a few special cases, theoretical equations have been derived for estimating the voltage-recovery characteristics of practical systems, and are included in this section.

Parallel Circuit Data. The data in Figure 14 were obtained for a total of 16 miles of line, connected as two 8-mile lines in parallel, and as one 4-mile and one 12-mile lines in parallel. These are compared with the general study data for a single 16-mile line. The following conclusions are evident:

1. The time to 90 per cent voltage is a minimum with a single line.
2. The time to maximum recovery voltage is a minimum with more than one line in parallel.

Because of conclusion 2, calculations were made for the case of an infinite number of lines in parallel, which was done by neglecting all line inductance and representing the lines by lumped capacitances. This data, for a single-line-to-ground fault on a 2-ohm 16-mile system is given in Table II. The maximum voltages vary between 168 and 183 per cent, and compare favorably with the 175 per cent obtained in the general study for single-line-to-ground faults. The times to maximum voltage range between 90 and 103 microseconds, the shorter time being obtained with the smaller conductor on a 3-wire system. The time to 90 per cent voltage is also a minimum for this same system.

Whenever line inductance can be neglected, the significant recovery voltage times vary as $\sqrt{XM}$, where X is the 60-cycle source reactance and M is the total miles of connected line, assumed to be equal on the three phases. Curve I, Figure 7, is the calculated curve for times to maximum voltage for a single-line-to-ground fault on a number 6-conductor, 3-wire system. This straight-line curve, approaches the analog computer data for X/M ratios above 1.0, even though the computer data were obtained for a single line, and the calculated curve applies for an infinite number of lines in parallel. This shows that line inductance has little effect on the times to maximum voltage for large X/M ratios. The significant time to maximum voltage for the case of a 4-mile line and a 12-mile line in parallel was taken from Figure 14, and plotted in Figure 7. It will be observed that this point falls closer to curve I than to the single-line curve. As most systems will have a multiplicity of circuits, it is suggested that curve I be used for estimating times to maximum voltage, regardless of circuit arrangement. Curve II, Figure 7, represents the times to 90 per cent voltage for the case of an infinite number of parallel circuits. The times to 90 per cent and maximum voltage, for the limiting case of an infinite number of feeders in parallel, can be estimated as follows:

$$T_{0.9}=7.7\sqrt{XM} \text{ microseconds} \qquad (1)$$

$$T_m=15.9\sqrt{XM} \text{ microseconds} \qquad (2)$$

where X is the 60-cycle source reactance in ohms, and M is the connected overhead line in miles per phase, including trunk feeders and laterals. The constants in the equations were derived from the calculated times in Table II for a number 6 conductor, 3-wire system.

The computer data in Figure 7 fall close to curve II for X/M ratios larger than approximately 1/3. Below this ratio, the times for a single line are not a function of line length, but only of source reactance. The minimum times were obtained for single-line-to-ground faults on the sending-end bus, and the recovery voltage reached the 90 per cent values before reflections returned from the open end of the line. These times therefore vary directly with the 60-cycle source reactance, and follow curve III.

With several long feeders in parallel, and a low source reactance, the times to 90 per cent voltage will be independent of line length, and will vary directly with source reactance and with the number of feeders connected to the source bus. These cases could be represented in Figure 7 by additional curves in parallel with curve III, and with the times for a

given X/M ratio increased directly with the number of parallel feeders. The times to 90 per cent voltage for these long-line cases, where line reflections can be neglected, can be estimated from the following relation

$$T_{0.9}=13.8\ NX \tag{3}$$

where X is the 60-cycle source reactance in ohms and N is the number of long feeders in parallel. The constant in the equation is the calculated time to 90 per cent voltage for a system consisting of a 1-ohm source and a single number 6 copper overhead circuit.

In any particular case being studied, the time to 90 per cent voltage should be calculated by equations 2 and 3, and the minimum time thus obtained should be used. This procedure will result in conservative results for systems normally encountered in practice.

Impedance-Grounded Systems

Additional studies were made to show the effect of grounding methods on the voltage-recovery characteristics of distribution systems. As broad general studies of impedance-grounded systems were outside the scope of this paper, the data included should be used to indicate trends only. All investigations, excepting one, were based on a simple system representation in which line inductance could be neglected. This corresponds to actual systems having large X/M ratios, or a number of parallel circuits on a common supply bus.

Reactance-grounding. With a reactance-grounded source and the larger conductor sizes, resistance does not have any important influence on the significant voltage-recovery characteristics of a system. Assuming a given X_0/X ratio for the source, the times to 90 per cent voltage, with large X/M ratios, and to maximum voltage will vary directly with $\sqrt{XM}$. The time to 90 per cent voltage will vary directly with X if the X/M ratio is small. This allows plotting the data for reactance grounded systems on a general basis.

The data in Figure 15(A) apply for a single-line-to-ground fault on a 3-wire 4/0-conductor reactance-grounded system. The dashed curve, plotted from computer data, shows oscillations in the time to 90 per cent voltage as a function of the X_0/X ratio. These variations are present because the ratio of the positive- and zero-sequence natural frequencies vary with X_0/X. Similar variations would be produced by varying the X/M ratio of the system. For this reason it was concluded to draw a smooth curve below the computer data, and to use this curve in determining the time to 90 per cent voltage for large X/M ratios, where line inductance can be neglected. The $T_{0.9}/M$ curve was calculated by neglecting line reflections, and applies for low X/M ratios. In any given case, the time to 90 per cent voltage should be calculated by both methods, and the minimum time used.

The times to maximum voltage and the maximum voltages were calculated for X_0/X ratios that gave zero-sequence natural frequencies that were integral multiples of the positive sequence natural frequencies, in order to obtain the highest voltages. Smooth curves were then drawn through the calculated values. These calculations neglected line inductance, which case gives the minimum times to maximum voltage.

Figure 15(B) gives similar data for a double-line-to-ground fault on a reactance-grounded system. The times to 90 per cent voltage, neglecting line inductance or line reflections, were substantially constant over the reactance-ratio range considered, and so average values were used. The time to maximum voltage increases very slowly with increases in the X_0/X ratio. The maximum-voltage curve was estimated by multiplying the measured voltage of 180 per cent, for X_0/X = 1.0, by the calculated, sustained line-to-ground voltage during a single-line-to-ground fault. The computer data obtained by neglecting line inductance, falls close to the calculated curve, indicating that the increase in voltage is due to the higher dynamic voltage across the first phase to clear.

Ungrounded Systems. The data in Figure 15, for X_0/X ratios of infinity, apply for ungrounded systems. The recovery-voltage curve, following a single-line-to-ground fault on an ungrounded system, is a fully-offset cosine function, with 3,900 microseconds to 90 per cent voltage and 8,330 microseconds to 200 per cent voltage. The computer study gave a maximum recovery voltage of 320 per cent, following a double-line-to-ground fault, neglecting line inductance. The times associated with the recovery-volt-

Table II. Calculated Recovery-Voltage Data for a Solidly-Grounded System Consisting of a 2-Ohm Source and 16 Miles of Line

Conductor Size	System	$T_{0.9}$	T_m	E_m
#6	3-wire	43.5	90	175
4/0	3-wire	47.3	95	168
#6	4-wire	45.3	94	183
4/0	4-wire	49.6	103	180

The above data were calculated for a single-line-to-ground fault, neglecting loss and line inductance.

(b) 2 L-G FAULTS

age transients can be calculated using the data in Figure 15.

Resistance Grounding. The recovery-voltage data for resistance grounded systems cannot be generalized to the same extent as for reactance-grounded systems. For this reason, the information included here is of rather limited application, especially for single-line-to-ground faults.

The data in Figure 16 were obtained in an analog computer study of a 53.3-mile 4/0-conductor 3-wire system, having a source positive-sequence reactance of 60 ohms and a zero- to positive-sequence reactance ratio of unity. Line inductance was neglected. It is evident that resistance grounding decreases the severity of the recovery-voltage transients, following a single-line-to-ground fault, by increasing the times and decreasing the maximum voltages. This same trend would be obtained with other source reactances and line lengths.

The data in Figure 17 for double-line-to-ground faults, have been plotted on the same general basis used for reactance-grounding. This appears to be permissible, even though not theoretically correct, because the zero-sequence resistance does not have large effects on the recovery-voltage times. For example, $T_{0.9}/\sqrt{XM}$, which applies when line inductance can be neglected, does not vary appreciably with the R_0/X ratio. The plotted points, obtained for a 60-ohm, 53.3-mile system, fall very closely to the straight line curve, which applied for a solidly-grounded system (from curve II, Figure 7). The $T_{0.9}/X$ value in Figure 17 was taken from curve III, Figure 7. Both of these relations should be employed in estimating the time to 90 per cent voltage, in any particular application and the minimum value used. The times to maximum voltage were obtained for two systems having widely different XM products. Even though one XM product is over 11 times the second product, the $T_m/\sqrt{XM}$ values differ by less than 20 per cent. Indications are that this value will never be less than the corresponding value for a solidly-grounded system (curve I, Figure 7), which is plotted as a solid line in Figure 17.

The R_0/X ratio and the XM product have considerable influence on the maximum voltages, following double-line-to-ground faults. The highest voltages were obtained with the XM product of 3,200, which is larger than expected in practice. Practical XM products and R_0/X ratios would probably limit the voltages to values not much above the 205 per cent obtained for solidly-grounded systems.

Fault Resistance. Recovery voltage data, including the effects of fault resistance, were obtained for a 16-mile 3-wire 4/0-conductor system having a 16-ohm, solidly-grounded source. Line inductance was neglected. The single-line-to-ground fault data in Figure 18(A) shows that fault resistance decreases the maximum voltage produced, and increases the times to 90 per cent voltage. The times to maximum voltage are decreased slightly by fault resistance.

The double-line-to-ground fault data in Figure 18(B) do not indicate any important changes in the times to 90 per cent voltage, with fault resistance. The times and magnitudes associated with the maximum voltages increase with fault resistance, which means that fault resistance should be given consideration on 3-wire systems. On 4-wire systems, fault resistance is, in effect, in parallel with the neutral wire and would have less effect on recovery voltage than in 3-wire systems.

Discussion

H. R. Tomlinson (New England Power Service Company, Boston, Mass.): To correlate with the range used by the author, an investigation was carried out by the writer on the X to M ratio of several typical substations on the system with which he is associated. (See Table I of the discussion.) All feeders from the substations which were considered are overhead. Five stations have 2,300-volt ungrounded feeders and two stations have 4,000-volt ungrounded feeders. Total miles of equivalent 3-phase overhead circuits connected to the busses ranged from 21 to 64 miles. The minimum value of ohms of supply system reactance to the distribution substation bus, based on the nominal voltage of that bus, is 25.8×10^{-3} ohms and the maximum value 295×10^{-3} ohms, a range of approximately 1-to-11.

The X to M ratio for the 2,300-volt systems varies over a range of 1-to-15 with a minimum value of 4×10^{-4} ohms per mile and a maximum value of 61×10^{-4} ohms per mile. Intermediate values are 15×10^{-4}, 25×10^{-4}, and 48×10^{-4} ohms per mile. The two values for the 4,000-volt systems are 74×10^{-4} and 63×10^{-4} ohms per mile.

Table I

Name of Substation	Voltage	X	M	X/M
Gardner	2,300	0.0787	52.23	0.00151
Franklin	2,300	0.1225	47.47	0.00258
Uxbridge	2,300	0.0258	64.40	0.000400
Palmer	2,300	0.1285	21.0	0.00610
Rumford	2,300	0.210	43.2	0.00487
Arctic	4,000	0.295	39.6	0.00745
Knightsville	4,000	0.230	36.26	0.00635

X = ohms of supply system reactance to the distribution substation bus, based on the nominal voltage of that bus.

M = miles of equivalent overhead circuit connected to that bus.

I. B. Johnson, J. W. Kalb (General Electric Company, Pittsfield, Mass.): In comparing the results obtained by Witzke on the voltage-recovery characteristics of distribution systems with a similar study that we have made, we find a number of observations and conclusions that are in agreement. Whereas Witzke's study was primarily analytical involving the representation of systems in miniature, our study in addition to the miniature system included results obtained from a rural distribution system as basis for comparison, and as a basis for demonstration of the validity and ability of the miniature system to reproduce and extend the scope of the study. Comparing the miniature system results, these points of agreement were noted:

1. That in general the maximum recovery voltage to be expected for single-line-to-ground fault is approximately 175 per cent of line to neutral crest voltage.
2. That maximum recovery voltages are not obtained necessarily for faults at the sending-end bus. Witzke in his paper gives an example of this for an 8-mile line. One of our observations was made for a total of 220 miles of branched lines on the faulted phase.
3. That for small line conductors there was a tendency for the maximum recovery voltage to occur for sending-end faults.
4. That conductor size is effective in determining the phase angle of the fault path.
5. That in a broad general sense for short lengths of line of the order of six to eight miles in length involving single-line-to-ground faults, the time to maximum crest recovery voltage T_M and the time to nine-tenths normal crest voltage $T_{0.9}$ can be expected to be of the order of 150 and 70 microseconds, respectively when connected to an 8-ohm source.
6. That since distribution systems in general are a complex network and that since even for straightaway unbranched lines the determination of the maximum severity of the recovery voltage is a complex problem, the formulation of comprehensive conclusions requires further data and study.

A question for further discussion is this: Is or is not the degree of damping important when no lines or short lines connected to the substation bus are involved wherein relatively very high-frequency recovery voltages are experienced? Witzke makes two statements with regard to damping in his study; namely:

1. Theoretical considerations and analog computer studies showed that the X/M ratio of a distribution system, where X is the 60-cycle source reactance in ohms and M is the miles of connected line per phase, may be used as the fundamental variable in recovery-voltage studies, whenever the system natural frequencies are high by comparison to the fundamental system frequency, and losses are not a significant factor in determining the voltage-recovery characteristics.
2. The resistance of the source was represented by the inherent losses of the reactors used to represent the source reactance. The reactance-to-resistance ratio of these reactors was always higher than the probable ratio for distribution or power transformers, over the entire range of frequencies encountered in the study.

In comparing the magnitudes of the recovery voltages, the attenuation used in our miniature system study is greater than the results obtained by Witzke. Yet the attenuation evident in the field investigation is greater than that in our miniature system, particularly for cases of little or no line remaining connected to the substation bus. At the substation transformer bus with no lines emanating therefrom where the X/M ratio, or its equivalent, becomes very large and where the most severe recovery voltages might be expected to occur, the maximum recovery voltage from the field system study did not exceed normal crest voltage thus indicating a large amount of damping.

It is doubtful that this damping can be ascribed completely to after-conduction of the arc gases in the current interrupting device, since in many other instances of fault current interruption at the terminals of large kilovolt-ampere transformers, maximum recovery voltages of the order of only 125 per cent of crest line to neutral voltage have been recorded. To those who design and apply distribution system protective devices, this information in the region where the most severe recovery voltages are to be expected is extremely important. However, the question for this case, or any other similar case, of the relative amounts of damping contributed by the transformer, protective device or other factors remains unanswered.

It appears, therefore, that future studies and investigations might profitably be directed toward evaluating the damping factors that may be present in limiting the severity of the recovery voltages in those cases which apparently should result in severe recovery voltages.

A. M. Opsahl (Westinghouse Electric Corporation, East Pittsburgh, Pa.): Tests on expulsion lightning arresters require laboratory circuits to simulate the service conditions. These circuits must be concentrated in a relatively small space. It is impractical to attach several miles of overhead line to the laboratory transformer to modify the recovery voltage. It is impossible to have individual transformers which match all sizes that will be encountered in service. Reactors in the primary or secondary of the available test transformers can limit the current within the rating of the lightning arrester. Capacitors connected in shunt with the expulsion lightning arrester under test can simulate the effect of line capacitance in slowing down the recovery voltage following an operation which is initiated by a surge and followed by a half cycle of short circuit current.

Figure 1 of the discussion shows the voltage and current relations during the operation of an expulsion lightning arrester under a controlled laboratory test. Normal or generated voltage appears across the lightning arrester. At crest voltage, a surge is discharged through the lightning arrester and the voltage across the lightning arrester drops to a very low value establishing the follow current as limited by the impedance of the circuit at power frequency. Follow current through the lightning arrester causes some volatilization of fiber from the walls of the discharge path. The arc voltage

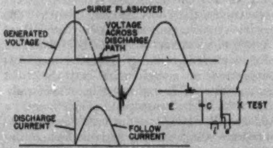

Figure 1. Voltage and current relations during the operation of an expulsion lightning arrester

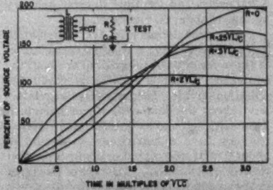

Figure 2. Natural frequency recovery voltage circuit characteristics

Units are: microhenries, microfarads, microseconds, and ohms

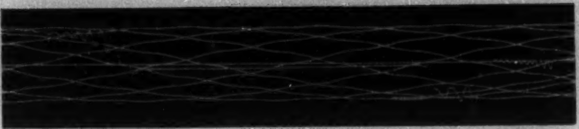

Figure 3. Section of cathode-ray oscillogram showing natural frequency oscillation on energizing the circuit, and recovery voltage oscillation following current interruption

builds up and may reduce the follow current. At follow current zero, the voltage across the lightning arrester begins to recover to generated voltage. However, the system is composed of an inductance in the form of the short-circuit reactance, and a capacitance in the transformer bushing and winding as well as any added capacitance. Charging the capacitance from line-to-ground through the circuit inductance causes the recovery voltage to oscillate around the instantaneous generated voltage at the natural frequency of the inductance-capacitance network. The network is in effect shocked into oscillation. The first half cycle of that oscillation determines the time to first crest of the recovery voltage. The lightning arrester discharge path must develop dielectric strength more rapidly than the voltage recovers or a second half cycle of follow current will be established.

The first half cycle of the recovery voltage is shown in more detail in Figure 2 of the discussion. The simple circuit of a single transformer energized from an infinite bus will serve to illustrate most cases as a single frequency oscillation from such test circuits is most frequently measured. The capacitance CT of the winding determines the shortest time to recovery voltage crest that can be expected from the transformer. The time to crest recovery voltage with no damping or loss in the circuit is $3.14\sqrt{L/C}$ as shown by the curve marked $R=O$. The recovery voltage reaches twice normal or generated voltage crest at the instant of follow current zero. If the inductance L is expressed in microhenries and the total capacitance C is expressed in microfarads, the time is in microseconds. For example, a 9,000-volt testing transformer delivering 560 amperes short circuit current has an inductance of 42,500 microhenries, and a capacitance of 0.0067 microfarad in the transformer winding and 0.002 microfarad in the cathode-ray oscillograph potentiometer. The natural frequency of the circuit is 8,200 cycles and the time to crest recovery voltage is about 60 microseconds.

Power transformers in the distribution voltage classes have a winding capacitance[1] in the order of 0.006 microfarad or about the equivalent of half a mile of overhead distribution circuit. Feeder voltage regulators have about the same capacitance from line-terminal-to-ground as transformers. Feeder reactors have a capacitance-to-ground of about 0.0001 microfarad or about 2 per cent that for transformers. The type of reactance in the source to a distribution circuit plays a part in determining the time of recovery voltage if the line is short enough that the addition of another half mile of line makes an appreciable difference.

In the laboratory test circuit, adding a capacitance C is the equivalent of adding a section of a distribution circuit. It increases the time-to-crest of the recovery voltage. By the addition of a resistance in series with the added capacitance, a degree of damping can be introduced. The inherent damping or loss in circuits without added capacitance is such that the recovery voltage is about 180 per cent of source voltage which in Figure 2 of the discussion is the equivalent of a resistance between $0.25\sqrt{L/C}$ and zero. Any resistance R added to the circuit reduces not only the crest of recovery voltage, but changes the wave shape so that the time to 90 per cent of source voltage $T_{0.9}$ will be shorter than in proportion to the time-to-crest recovery voltage T_m. This approaches more nearly the shape of the recovery voltage waves as determined by the analog computer studies, given in the author's paper and in field measurements.

A more exact representation of the rise of recovery voltage to the 90 per cent of normal could be obtained by splitting the reactance L into two parts and dividing the capacitance in two parts to provide a high and low frequency component of recovery voltage.[2] This is too complicated for use in these circuits where the required time to crest recovery voltage for all service conditions cannot be determined too accurately, but some time value must be set as the most severe condition to be regarded as standard for test purposes.

Previous studies indicate that recovery voltages can reach a maximum of 180 per cent of normal line-to-ground voltage following a single-line-to-ground, and 200 per cent of normal following double-line-to-ground faults on a grounded neutral system. These voltages on a 7,200/12,400-volt grounded neutral system would correspond to 144 and 160 per cent recovery voltage in a laboratory circuit using a 9,000-volt rms test voltage to match the standard lightning arrester rating. The circuit resistance R required to limit the recovery voltage to 160 per cent of normal is approximately $0.375\sqrt{L/C}$ assuming the inherent loss in the circuit and the transformer capacitance C_T can be ignored. A measurement of the recovery voltage must be made to check this approximate calculation.

Figure 4. Cathode-ray oscillogram of voltage during two follow current interruption tests

Such a selected percentage recovery voltage with a selected length of short distribution line, say 10 miles, in the case of the 7,200/12,400-volt class, could correspond to the most severe recovery voltage to be regarded as standard in service and to be required in a standard test. The capacitance of 10 miles of line is 0.13 microfarad. The actual time to crest recovery voltage is dependent on the reactance of the source as well as the capacitance of the line.

In service, any additional line length reduces the recovery rate or increase time to crest. Any arc voltage in the lightning arrester discharge path and resistance in the short circuit impedance will displace the current zero from the crest of generated voltage and reduce the maximum recovery voltage below the standard circuit condition. In fact, almost any other circuit changes are in the direction to reduce the severity of the recovery voltage.

The test circuit must be adjusted independently of the effect of a lightning arrester on the circuit. One method of making this check is to energize the primary of the transformer at crest of applied voltage. The circuit is shocked into natural frequency oscillation which is not affected by the lightning arrester. An oscillograph capable of responding accurately to the natural frequency of the circuit will record the recovery voltage magnitude and shape.

Figure 5. Cathode-ray oscillogram of voltage during two follow current interruption tests

Recovery voltage modified by capacitance and resistance

The oscillogram in Figure 3 of the discussion is interesting in that it illustrates the natural frequency of the test circuit without the effect of the lightning arrester, and with the effect of the lightning arrester. There were several revolutions of the film drum after the lightning arrester operation so there are a number of confusing lines which must be ignored. The length of the film covers about one-half of a 60-cycle wave. At the left, the circuit breaker between the generator and the transformer primary was closed at about crest voltage. The transformer was shocked into natural frequency oscillation, the voltage reaching about 180 per cent of the normal voltage at the instant. At the end of this oscillation, the surge generator discharged through the expulsion lightning arrester and the voltage dropped toward zero. After the surge current, the voltage attempted to recover without establishing follow current. The recovery voltage overtook the dielectric recovery strength of the lightning arrester under this condition, and follow current was established. Arc voltage built up with time during follow current and current zero occurred before power voltage crest. The lightning arrester withstood the recovery voltage. The surge timed to strike very early or late in the half cycle of power volt-

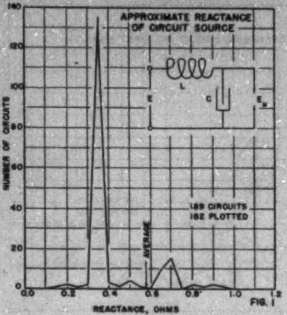

Figure 6. Approximate reactance of circuit source

age may not establish follow current due to this tendency of the expulsion to withstand recovery voltage following a surge discharge.

The cathode-ray oscillogram in Figure 4 of the discussion records the voltages during two operations of an expulsion lightning arrester on a 9,000-volt test transformer. There was no capacitance added to modify the recovery voltage. The follow current zero was ahead of generated voltage crest due to the relatively high arc voltage of the lightning arrester. The frequency of the recovery voltage is 8,200 cycles, and the time to maximum recovery voltage 60 microseconds.

The cathode-ray oscillogram in Figure 5 of the discussion records the voltage during two tests of an expulsion lightning arrester. The test transformer is the same as in Figure 4 of the discussion, but a reactor has been added to reduce the short circuit current from 560 to 150 amperes. A load capacitance of 0.08 microfarad increased the time-to-crest recovery voltage from 60 to 250 microseconds and a resistance of 1,000 ohms in the capacitor circuit limited the recovery voltage to 140 per cent of normal.

These oscillograms illustrate the tests that can be made in the laboratory with and without modification of recovery voltage. The determination of the complete dielectric recovery voltage curve for all expulsion lightning arresters at all currents is not feasible. A laboratory test circuit set up to duplicate the most severe conditions which can be justified on the basis of system studies can be established as a withstand test which is made quite readily. The recovery voltage in other studies has been expressed in terms of volts per microsecond. This terminology applied to an expulsion lightning arrester testing standard is awkward.

A standard circuit to control recovery voltage for expulsion lightning arrester testing could be specified as requiring:

1. A power source having a voltage equal to the maximum voltage rating of the lightning arrester.

2. A source reactance limiting the short circuit current within the lightning arrester rating.

3. A capacitance across the lightning arrester equivalent to the shortest length of distribution circuit that system studies indicates to be in common use.

4. A resistance in series with the capacitance to limit the crest recovery voltage to a value 160 per cent of the 60-cycle test voltage crest.

Leonard M. Olmsted (Duquesne Light Company, Pittsburgh, Pa.): The two principal characteristics of recovery voltage are the maximum voltage and the time to maximum voltage. Witzke has reported the results of analyses and tests with the analog computer for several types of distribution circuits over a wide range of source reactances, line lengths, conductor sizes, and fault locations, which indicate that the maximum voltages usually are on the order of 175 per cent of normal crest voltage for single-line-to-ground faults and 205 per cent for double-line-to-ground faults. The purpose of this discussion is to present an analysis of voltage recovery time on a typical 4,160-volt distribution system consisting of 225 ungrounded circuits with lengths up to 44 miles and a great variety of combinations of source reactance, multiconductor cable, number and location of branches, and transformer locations. This total number of circuits includes 23 which are all cable and therefore omitted, and 19 other circuits which are fed from six common busses without individual reactors and hence were grouped into an equivalent six; the number of circuits considered for this investigation is thus established as 189.

It has been shown that the recovery characteristics of a circuit may be represented by the single line analogy shown in Figure 6 of the discussion, where *L* represents the inductance of the source, *C*, the equivalent shunt capacitance of the circuit, *E*, the impressed voltage, and E_R, the recovery voltage. It is more convenient to measure *L* in terms of the common 60-cycle reactance. The sources of the 189 circuits included in this survey have the reactances plotted in Figure 6 of the discussion; the most frequent value being 0.345 ohm which is a very common current-limiting reactor. Largely because of the higher impedance of a considerable number of unit stations, however, the system average is 0.58 ohm. The lowest reactance, 0.132 ohm, applies to one power circuit directly connected to the bus of a large substation.

The fundamental effect of the overhead line is to establish the value of capacitance. This is measured in terms of the circuit miles of 3-phase equivalent to the summation of the 1-, 2-, and 3-phase open-wire portions of the circuit. The values determined from this survey range from 0.3 to 44.4 miles, averaging 8.8 miles, with the distribution plotted in Figure 7 of the discussion. The open-wire distance to the most remote transformer on each of these circuits shows a range from 0.0 to 11.7 miles with an average of 2.8 miles as plotted in Figure 8 of the discussion. The distance to the first transformer varies from 0.0 to 3.2 miles with an average of 0.29 mile as plotted in Figure 9 of the discussion. The number of major branches from these circuits varies from 0.0 to 15, the latter figure derived from a group of five circuits which are fed without reactors from a common bus. The average number of branches is shown by Figure 10 of the discussion to be 3.5. The open-wire distance from the source to the first branch is plotted in Figure 11 of the discussion, which shows an average of 0.37 mile with a large number less than 0.025; the extreme distance is 3.4 miles. These considerations

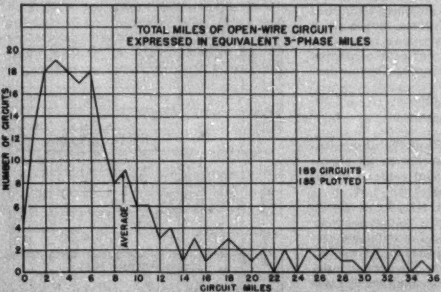

Figure 7. Total miles of open-wire circuit expressed in equivalent 3-phase miles

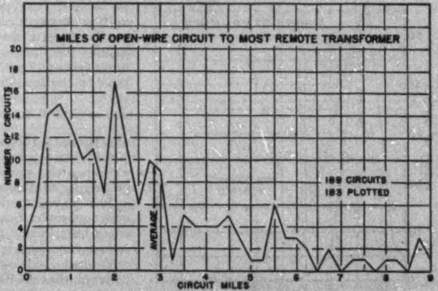

Figure 8. Miles of open-wire circuit to most remote transformer

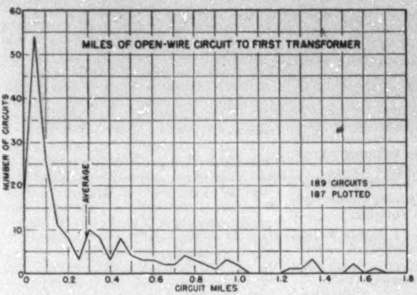

Figure 9(left). Miles of open-wire circuit to first transformer

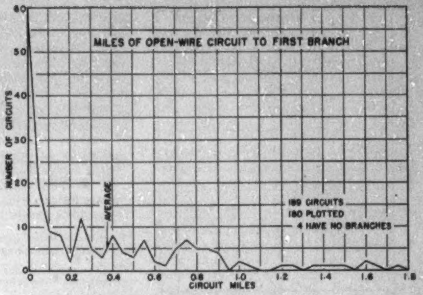

Figure 11 (right, above). Miles of open-wire circuit to first branch

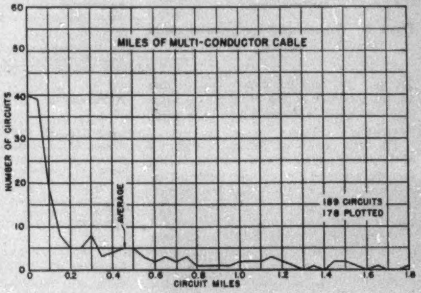

Figure 12 (right). Miles of multiconductor cable

indicate that the mileage of open-wire circuit is concentrated usually at a relatively short distance from the substation, which seems to justify the assumption that recovery voltage calculations can be based upon lumping the open-wire circuit capacity at the substation terminal.

Because of its relatively high capacity, compared with open-wire circuits, the amount of multiconductor cable is a very important factor The miles of cable on these circuits range from 0.0 to 4.8 miles with an average of 0.46 mile as plotted in Figure 12 of the discussion, showing a large number of circuits with less than 0.15 mile. Inasmuch as 0.15 mile of 3-conductor 350,000 circular mil cable is approximately equivalent to the capacity of nine miles of open-wire, it is clear that cable cannot be neglected in calculations of recovery voltage. Most of this cable is connected directly to the substation terminals; hence it is correctly represented by assuming all capacity to be lumped at that point. The combined capacitance of cable and open-wire, expressed in terms of the equivalent open-wire mileage, ranges from 0.30 to 304.6 miles with an average of 36.7 miles, as plotted in Figure 13 of the discussion.

Having determined the average of these seven characteristics of this group of circuits, it is interesting to observe the map of the circuit which most nearly approximates them. This circuit is shown as Figure 14 of the discussion and appears to be very typical.

The time to maximum recovery voltage has been calculated for each of these 189 circuits individually, using the method proposed by Witzke

$T_M = 15.9\sqrt{XM}$ microseconds

The M is shunt capacitance of wire and cable, expressed in equivalent 3-phase miles of open-wire. These values are plotted in Figure 15 of the discussion, showing a range from 14 to 120 microseconds (omitting three offscale values up to 205 microseconds), with a predominant value at approximately 40 and an average of 55 microseconds. T_M probably is the most significant time in voltage recovery calculations, but a point on the slope of the curve may have some value; the time to 90 per cent of normal line-to-ground crest voltage has been calculated by the equation

$T_{0.9} = 7.7\sqrt{XM}$ microseconds

and plotted on Figure 15 of the discussion, which shows a range of 6.8 to 99 microseconds with a predominant value of 20 and an average of 25 microseconds.

This survey should be considered only as a first approximation to the voltage recovery characteristics of a typical distribution system, as experience may indicate the need for refinements. It serves to demonstrate, however, that a 4,160-volt unigrounded system has surprisingly severe recovery voltage characteristics, in many cases worse than any shown by Witzke for star systems. The average circuit reaches 175 per cent of line-to-ground crest voltage in 55 microseconds, and one requires only 14 microseconds. Evidently present types of protective equipment have adequate provision for such recovery voltages, as their operating record appears generally satisfactory. The effect upon the design of future types of equipment is difficult to predict, however,

and appears to be a subject for careful investigation. It may prove necessary to establish zones for the application of certain devices within their voltage recovery capabilities, similar to present practice with the interrupting capacity of expulsion cutouts. It is highly desirable to avoid this complication if it is economically possible to design equipment for unrestricted application.

E. Beck (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The papers presented on this subject are of great value. One of the services which they, probably supplemented by other work to follow, will render is the possibility of standardizing on duty cycle tests for distribution lightning arresters of the expulsion type. Such tests are, of course, made already by the various manufacturers of these devices but no standards for recovery voltage conditions exist. It appears that for the most part the service experience with expulsion lightning arresters has been highly satisfactory. The company with which this discussor is associated has manufactured such devices for about 17 years.

It is too soon to come to definite conclusions about the exact content of a standard. The complexity of the recovery voltage problem and the wide variations encountered in the studies indicate that the selection of a standard for laboratory test circuits will require considerable thought and perhaps compromise. Under certain system conditions and for certain locations of expulsion lightning arresters the recovery conditions may be exceedingly severe while for others they are more or less mild. The question will arise whether the test conditions selected shall be such that any expulsion lightning arresters will perform in the laboratory under the most severe conditions that may occur anywhere on any distribution system or whether a compromise should be adopted based on probabilities. This decision will affect design, construction, and costs.

The fact that the expulsion lightning arrester is affected by the recovery voltage characteristics of a system and the valve lightning arrester is not, may affect the decision. For example, it might be said that for some systems of large capacity, if all possible conditions are to be met, valve arresters should be used in the substations although expulsion lightning arresters are used everywhere else. For those who still entertain reservations about the ability of modern valve-type distribution lightning arresters to handle severe lightning discharges, it should be said that in a substation the duty on a valve-type lightning arrester is less severe than out on the line because of the presence, close by, of the

source transformer which acts as a shunt for lightning currents of long duration. There appears to be no significant indication from service experience that one type is superior to the other.

In the approach to a standard these matters should be considered. It is quite possible to arrive at a standard which, in order to satisfy a condition whose occurrence in the field is unlikely, imposes economic penalties on the general use of a device under the conditions that predominate. It is also possible to temper the standard with a consideration of the probabilities and take whatever slight risk may lurk in those cases where the conditions defined in the standard are exceeded. It is further possible to approach the matter with the fact in mind that there already are available two types of lightning arresters for distribution systems.

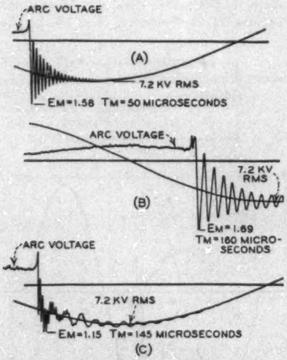

Figure 18. Effect of adding capacitance to a laboratory test circuit on recovery voltage

(A) Recovery voltage of circuit without added capacitance
(B) Recovery voltage of circuit with capacitance added in parallel to test specimen
(C) Recovery voltage of circuit with capacitance added in parallel to current-limiting reactor

H. O. Stoelting (Line Material Company, South Milwaukee, Wis.): This paper presents the first data on severity of recovery voltages on distribution systems. This discussion compares the recovery voltage on distribution systems with the circuits used for testing of fuse cutouts and expulsion lightning arresters. The effect of changing the test circuit constants on recovery voltage also are illustrated.

Recovery voltage can be defined as the charging of a capacitance through an inductive circuit. A simple recovery voltage circuit is shown in Figure 16(A) of the discussion. All inductance of the circuit is assumed lumped as shown and resistance is for the moment assumed negligible.

The current and voltage relationships for the circuit are shown in Figure 16(B) of the discussion. The curves shown are as follows:

e_G = generator voltage
i = current through the switch
e_L = voltage across the inductance
e_C = voltage across the capacitor

Since the circuit is assumed purely inductive, the current will lag the generated voltage by 90 degrees and the voltage across the inductance will be equal and opposite to the generated voltage. If the switch is opened at the normal current zero, both the generated voltage and the voltage across the inductance will be at crest, while the capacitor voltage is zero.

At the instant that the switch is opened the capacitor starts charging. The charging of the capacitor through the inductance causes the voltage of the capacitor to overshoot the normal voltage with a resulting oscillation due to an interchange in energy between the capacitor and the inductance.

If the circuit had no resistance the oscillations would continue indefinitely. Even slight amounts of resistance will cause the oscillations to damp out as shown.

Adding an additional series inductance and shunt capacitor to the right of the capacitor shown in Figure 16(A) of the discussion, will introduce a second frequency into the recovery voltage and make the analysis of the voltage relationships of the circuit much more difficult.

As Witzke pointed out, under certain conditions the reactance of the supply and the capacitance of the line of a distribution system can be considered as the inductance and capacitor respectively of Figure 1 of the discussion. Under most conditions, however, the reactance and capacitance to ground of the distribution lines must be considered as distributed. The usual method of representing this condition is by a large number of branches of inductance and capacitance in the circuit as was done in the transient analyzer studies.

A typical laboratory circuit for tests on 7.2-kv equipment is shown in Figure 17(A) of the discussion. This diagram shows only the elements of the circuit. The reactances and stray capacitances of the elements as shown in Figure 17(B) of the discussion are:

L_s = inductance of the supply line
C_s = capacitance of the supply line
L_r = inductance of the air core current limiting reactor
C_r = stray capacitance to ground of the reactor
L_t = leakage inductance of the transformer bank
C_t = stray capacitance to ground of the transformer bank
L_b = inductance of the bus
C_b = stray capacitance to ground of the bus

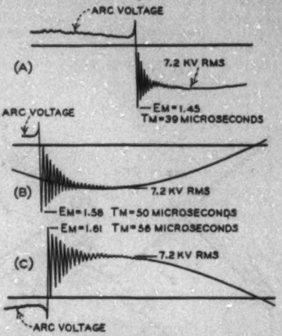

Figure 19. Effect of supply transformer kilovolt-amperes on recovery voltage of laboratory circuit of constant voltage, current, and power factor

(A) 200-kva single-phase supply transformer
(B) 300-kva single-phase supply transformer
(C) 400-kva single-phase supply transformer

An oscillogram of the recovery voltage of this circuit is shown in Figure 17(C) of the discussion. The recovery voltage crest of 1.61 times the normal voltage crest is somewhat lower than the maximum reported by Witzke.

The time to recovery voltage crest of 56 microseconds is of the same order as the minimum times to recovery voltage crest reported by Witzke. The studies in the paper presented indicate that a recovery voltage crest of 1.61 times the normal voltage crest associated with a time to crest of 56 microseconds is exceptional, so that the rate of rise of recovery voltage for the labora-

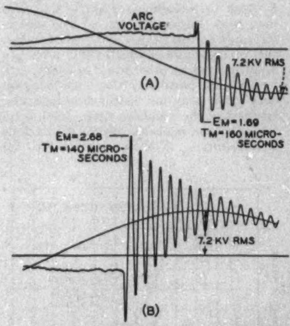

Figure 20. Effect of specimen arc voltage on recovery voltage of laboratory test circuit

(A) Low specimen arc voltage prior to recovery voltage
(B) High specimen arc voltage prior to recovery voltage

tory circuit is more severe than for the usual field condition.

The recovery voltage of Figure 17(C) of the discussion is predominantly single frequency, although a second frequency can be detected by drawing an envelope for the recovery voltage oscillations. In this instance, all of the inductance and capacitance branches of Figure 17(B) of the discussion with the exceptance of the inductance and capacitance of the supply transformer are negligible.

Studies were made to determine whether it would be possible to vary recovery voltages in the laboratory over the ranges found for distribution systems. The oscillograms of Figure 18 of the discussion were all taken on the same circuit but with a capacitor added to the circuit for Figures 18(B) and 18(C).

Figure 18(A) of the discussion shows the recovery voltage of the circuit normally used without a capacitor. Figure 18(B) was obtained by adding a capacitor in parallel to the test specimen. The added capacitance increased the recovery voltage crest 11 per cent and increased the time to crest by a factor of 3.2.

Figure 18(C) was obtained by adding a capacitance in parallel with the current limiting reactor. This change produced a double frequency recovery voltage of much lower crest value than for the other two conditions.

The time to 90 per cent of normal crest in this case is not a simple proportion of the time to crest as for the other two oscillograms of Figure 18 of the discussion.

A study of the effect of the supply transformer kilovolt-amperes on recovery voltage was undertaken to find out why some fuses would operate satisfactorily on one circuit, but would not clear on another circuit having the same voltage, current, and power factor, but with a different supply transformer kilovolt-amperes.

The oscillograms of Figure 19 were made on circuits having the same voltage, current and power factor, but with transformer banks of 200, 300, and 400 kilovolt-ampere single phase for Figures 19(A), 19(B), and 19(C) respectively.

Figure 19 shows that the effect of increasing the kilovolt-ampere of the supply transformer bank is to increase both the crest recovery voltage and the time to crest.

The analyzer studies reported by Witzke were made with a follow current interrupted at normal current zero. Under these conditions, the maximum recovery voltage can only theoretically reach a value of twice that of normal line voltage. The effect of arc voltage in a fault interrupting device is to force the current to zero before it normally would reach zero, and therefore increase greatly the severity of the recovery voltage.

The oscillograms of Figure 20 indicate the extent to which the arc voltage of a fault interrupting device can influence the recovery voltage of a circuit. Figures 20(A) and 20(B) were made on the same circuit, but with two different types of expulsion lightning arresters. The lightning arrester used in obtaining the oscillogram of Figure 20(A) had a very low rise in arc voltage just prior to current interruption compared to the lightning arrester used in the oscillogram of Figure 20(B). A slight difference in the design of the expulsion lightning arrester changed the recovery voltage crest from 1.69 to 2.68 times the normal voltage crest.

The influence of the arc voltage of a fuse or expulsion lightning arrester on the recovery voltage of a circuit must be recognized when recovery voltages are specified in industry standards. Since the recovery voltages of a circuit may be modified greatly by an arc interrupting device it will be essential to specify recovery voltage of the test circuit without the modifying influence of arc voltage.

R. H. Earle (Line Material Company, South Milwaukee, Wis.): This paper represents an excellent start on certain methods of test procedure which are of vital interest to manufacturers of circuit interrupting equipment for distribution systems.

In the development of fuses, circuit breakers, expulsion lightning arresters, and other apparatus whose function is to interrupt fault currents, it is highly desirable for the manufacturer to be able to reproduce actual service conditions in his laboratory.

Line voltage is known and can be reproduced accurately. The same is true of fault currents.

A third factor, namely, recovery voltage, is an entirely different question. Recovery voltage is the one that endeavors to restrike the arc after it has been extinguished by the device in question. The life of the device is measured frequently by the number of successful operations and this life is affected tremendously by the size and shape of these restriking voltages.

If during the development of a fuse for example, the designer chooses to test his device on recovery conditions that are too mild, the result may be a device which will prove inadequate in service. If on the other hand he chooses recovery conditions that are too severe, he may limit himself unduly from a design standpoint, and even abandon some designs which would be of considerable value if put into actual service.

These are not academic problems to the designer, but are of real practical importance in his daily work.

Industry standards have endeavored to take recovery voltages into account by requiring that rupturing tests be made at various low power factors. Low power factor is likely to be accompanied by severe recovery voltage conditions and low power factor is a step in the right direction in the testing of apparatus. Power factor is correlated with the recovery voltage only in a general way however and far more definite specifications are needed so that various laboratories can reproduce each others results.

Fortunately present day laboratory techniques and facilities permit the manufacturer to produce recovery voltages in his laboratory of almost any characteristics within reason, and he probably will have no trouble in establishing recovery conditions that are more severe than those occurring in all but the most exceptional service conditions.

The problem is to select suitable ones from the wide range of values available.

The work now in progress to determine the recovery voltages that actually exist under field conditions is of vital importance to the entire distribution industry.

R. L. Witzke: The number and character of the discussions presented indicates a real interest in the recovery voltage characteristics of distribution systems. The author expresses his appreciation for the comments given and for the valuable data included in the discussions. The acceptable agreement between field tests and miniature system studies, reported by Johnson and Kalb, is of particular interest because it substantiates our faith in the miniature system method of analyzing complicated system problems. When this method of analysis was introduced by Evans and Monteith[1] in 1937 there was considerable skepticism relative to its value. I feel we can now safely say it is an accepted tool in the field of power system engineering.

Johnson and Kalb point out that the attenuation used in their miniature system studies was greater than the attenuation shown by the analog computer results, and that the field studies showed still more damping. In the laboratory studies referred to by Johnson and Kalb, as well as in the analog computer studies, the losses in the transformer sources were represented by the inherent loss in the reactors used to represent the sources. The author kept the high-frequency reactance-to-resistance ratio of the sources to eight or ten, or higher, by a proper selection of miniature system constants, on the basis that the use of lower ratios might introduce losses not present on actual systems. A ratio of ten gives a damping factor of approximately 0.85 per half-cycle of a high-frequency oscillation, which value has been proposed[2] as being typical for terminal equipment. This decrement is in substantial agreement with the 180 per cent recovery voltage shown in Figure 3 of the discussion by A. M. Opsahl. The oscillograms in Stoelting's discussion show decrement factors per half-cycle of 0.88 in Figure 17 of the discussion and 0.92 in Figure 20 (B) of the discussion, which indicate even less decrement than we assumed.

As mentioned by Opsahl, the capacitance of terminal equipment, such as transformers and regulators, cannot be neglected if the total overhead line length is less than several miles. Also, as noted by Olmsted, many overhead circuits leave a substation through short sections of cable which may have appreciable capacitance. The influence of these terminal capacitances on the time to maximum recovery voltage can be estimated by converting the capacitances to an equivalent length of overhead line.

Opsahl's suggestion to base standards on a simple test circuit should be given consideration. The adequacy of a single-frequency test circuit must, of course, be established by further study of the relative shapes of the system recovery voltage and the protective device dielectric recovery characteristics.

The system data presented by Olmsted and Tomlinson will be extremely valuable in obtaining a broad picture of the recovery rates experienced on distribution systems.

Some Fundamentals of D-C Controlled Reactors with Resistive Load

H. F. STORM
ASSOCIATE AIEE

THE impedance of an iron-core reactor can be varied by introducing a magnetic bias, whose magnitude is controlled by a direct current in a separate winding. Such d-c controlled reactors commonly are called saturable reactors, or magnetic amplifiers.[1,2]

When a saturable reactor is connected to a load, as shown in Figure 1, an increase in the current in the d-c winding will increase the magnetic bias in the iron core. This will shift the alternating magnetic flux to a region of higher saturation, and hence decrease the impedance of the a-c winding. If the load consists of a resistance, a change in the direct current, and, therefore, in control power, is associated with a change in the load power. It will be found that a certain change in output power can be achieved with a much smaller change of input power; hence the term magnetic amplifier.

The ratio between output power and input power often is called the amplification factor. A typical value for the amplification factor is 100. To obtain amplification of higher order, several stages can be used, by feeding the d-c winding of the following stage with the rectified output current of the previous stage.[3] Another method for obtaining a higher amplification consists in rectifying the load current whose d-c component is used to aid the control-winding ampere turns;[4,5] amplification factors of 10,000 for a single stage can be obtained easily with ordinary transformer core materials.

The outward appearance of a saturable reactor is very similar to an iron-core transformer. Figure 2 shows a fairly large saturable reactor rated 25 kva, while Figure 3 shows one rated 1/2 volt-ampere.

Being an amplifying device, the saturable reactor, or magnetic amplifier, finds itself in competition with electronic amplifiers. There are fields of application where the choice is obvious, but in other cases a careful analysis will be required to decide which type of amplifier is preferable. At the present time, the application of the saturable reactor to frequencies of 100 kc and more is not considered practical because of excessive core losses. On the other hand, the amplification of small d-c voltages (millivolts) is a difficult matter for an electronic amplifier; however, a magnetic amplifier, being controlled by ampere turns, circumvents this difficulty.

Another distinct advantage of the magnetic amplifier over the electronic amplifier lies in the feasibility of applying a multitude of control signals simultaneously with freedom from voltage levels, by using several d-c windings acting on the same core. The comparative permanency of the components of magnetic amplifiers is an item which may sway the choice in favor of the magnetic amplifier.

Another advantage is seen sometimes in the high shock resistance of magnetic amplifiers; this feature, however, is not exclusive with magnetic amplifiers, as demonstrated by the electronic equipment used in the proximity fuse.

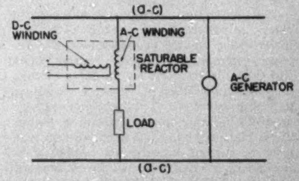
Applications

Saturable reactors often are used in theater lighting systems,[6] the incandescent lamps being connected in series with the a-c windings of the reactor. A similar arrangement is used for the heat control in electrical-resistance furnaces.[7] Firing circuits[8] for ignitrons and thyratrons use saturable reactors to effect phase shift. A great number of further applications are found in the literature.[9]

Basic Concepts

In its simplest form, a saturable reactor consists of an iron core with two windings: the a-c load winding, and the d-c control winding, Figure 4. The load winding is connected in series with the load, which may consist, for instance, of incandescent lamps, the control of their luminousity being the object. A d-c source of controllable magnitude energizes the d-c winding, thus effecting magnetic bias. Increasing the d-c current will increase the magnetic bias, shifting the core induction into regions of lower permeability, and thereby increasing the load current. The alternating current causes an alternating magnetomotive force f in the core. This induces an electromotive force in the d-c winding. If the inductor L were omitted, an appreciable amount of alternating current would flow in the d-c winding, causing unnecessary heat and power loss. However, the inductor L is undesirable. It involves extra cost and increases the time constant of the d-c control circuit, with attendant sluggishness of response on the part of the saturable reactors to a variation of the d-c control voltage, E_c.

Figure 1. Elementary diagram of d-c controlled reactor



Paper 49-55, recommended by the AIEE transformer committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted August 2, 1948; made available for printing December 22, 1948.

H. F. STORM is in the control engineering divisions of the General Electric Company, Schenectady, N. Y.

Figure 2. Two d-c controlled reactors

Each: 25 kva, 60 cycles, approximately 675 pounds, 23 inches long

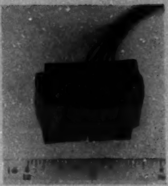


Figure 3. D-c controlled reactor with split core, 0.5 volt-ampere, 400 cycles

The induced electromotive force in the d-c winding consists of a large fundamental (line) frequency component and higher harmonics. By using two saturable reactors, they can be interconnected, Figures 5 and 6, so that the fundamental frequency components cancel out. Voltages of fundamental frequency still are being induced in the d-c windings between terminals Y_1 and Y_2. These voltages, being in phase with respect to the polarity marks, oppose each other, and a voltage of fundamental frequency does not appear across terminals 4–6. Thus, an inductor to suppress currents of fundamental frequency, as shown in Figure 4, becomes superfluous.

The control characteristics of the circuit in Figure 5 are shown in Figure 7. Supply voltage and frequency are held constant. Polarity of the direct current does not affect the load current I_{AB}.

The following paragraphs deal in greater detail with the harmonics appearing in core and windings, since these harmonics affect essentially the performance of the saturable reactor. Such interrelation is to be expected, because the operation of a saturable reactor is based on the nonlinearity of its inductance, and the higher harmonics are merely a manifestation of this nonlinearity.

For obvious reasons, the circuit in Figure 5 is called a parallel connection, whereas Figure 6 represents the series connection. It will become evident later that these two connections perform differently, the series connection being characterized by faster response.

As will be born out by oscillograms, the following simplifying assumptions can be made without impairing the validity of the conclusions:

1. The supply voltage is sinusoidal and the source impedance negligible.
2. Hysteresis effect and eddy current losses in the iron core are negligible.
3. Resistance and leakage reactances of the a-c windings are negligible.
4. The wave shapes are not affected greatly by the load resistance, hence the load is short circuited by closing switch *S*, Figures 5 and 6, further simplifying the theoretical analysis.

Next, polarities require definition:

Reactors *A* and *B* are identical; coil currents i_A, i_B, and i_{AB} are called positive when flowing in the direction of the associated arrows. Positive coil currents cause positive magnetomotive forces, f_A and f_B, whose positive direction also is indicated by the respective arrows. If a voltage pulse is applied which makes terminal *X1* positive with respect to terminal *X2*, a pulse will appear which is positive at terminal *Y1* with respect to *Y2* (as indicated by polarity signs); when current i_d flows in its positive direction, as indicated by the arrow, it causes a positive magnetomotive force, f_A, in coil *A*, but a negative magnetomotive force, f_B, in coil *B*.

Suppose an alternating voltage *e* is now applied to terminals *X1* and *X2*, Figure 5, and switch *S* closed. From Faraday's law the magnetic flux follows

$$e \quad \frac{d\varphi}{dt}N10^{-8} \tag{1}$$

$$\varphi=\frac{10^8}{N}\int edt \tag{2}$$

for

$$e=\sqrt{2}E\sin\omega t \tag{3}$$

and from equation 2

$$\varphi=-\frac{\sqrt{2}E10^8}{\omega N}\cos\omega t+\Phi_{dc} \tag{4}$$

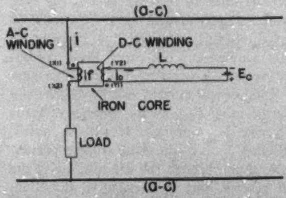

Figure 4. Schematic diagram of single, d-c controlled reactor

Substituting Φ_{ac}, for the factor of the cosine term

$$\varphi=-\Phi_{ac}\cos\omega t+\Phi_{dc} \tag{5}$$

where Φ_{dc} is an integration constant to be determined.

Equation 5 shows that the resultant flux φ in the core of the saturable reactor consists of a sinusoidally varying magnetic flux, φ_{ac}, which is lagging 90 electrical degrees behind the voltage, and which also may contain a superposed constant flux Φ_{dc}. These relations are shown graphically in the lower left-hand section of Figure 8. Subscripts *A* and *B* were added to refer to saturable reactor *A* or *B*, respectively. If Φ_{dc} is positive, the total flux φ_A will result; for a negative value of Φ_{dc} flux φ_B will result.

To produce the fluxes φ_A or φ_B, a magnetomotive force must be effective in the core. The relation between flux and magnetomotive force, in ampere turns, is shown in the graph in the upper left-hand section of Figure 8, and is referred to as magnetization line. For instance: for $\theta=150$ degrees, φ_A equals *MN;* the necessary magnetomotive force f_A is *PQ*. The magnetomotive force f_A is replotted, as a function of the electrical angle θ, in the upper right-hand part of the diagram. Because *PQ* was derived from the flux φ_A occurring at $\theta=150$ degrees, the same magnetomotive force *PQ* has to be erected over 150 degrees, as shown by *RS*. Other points of f_A are obtained in similar manner.

The magnetomotive force f_A may stem from ampere turns in the a-c winding, the d-c winding, or both. The currents in the windings of the saturable reactor can be determined from an analysis of the magnetomotive forces merely by dividing the magnetomotive force by the number of turns in the winding. To this end it will

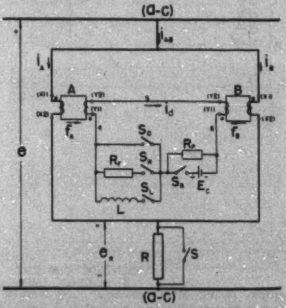

Figure 5. Parallel reactors with separate cores

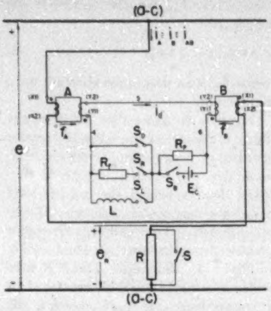

Figure 6. Series reactors with separate cores

be practical to break down the magnetomotive force of core *A* into three components: the constant term $F_{dc,A}$, the odd harmonics $f_{od,A}$, and the even harmonics $f_{ev,A}$. Applying a Fourier series[10]

$$f_A = F_{dc.A} + F_{1.A}\cos\theta + F_{2.A}\cos 2\theta + F_{3.A}\cos 3\theta + \ldots \quad (6)$$

If curve f_A were phase-shifted by 180 degrees and all signs were reversed, curve f_B would result

$$f_B = -F_{dc.A} - F_{1.A}\cos(\theta-180) - F_{2.A}\cos 2(\theta-180) - F_{3.A}\times \cos 3(\theta-180) + \ldots \quad (7)$$

Eliminating 180 degrees from equation 7

$$_B = -F_{dc.A} + F_{1.A}\cos\theta - F_{2.A}\cos 2\theta + F_{3.A}\cos 3\theta - \ldots \quad (8)$$

By addition and subtraction, one obtains

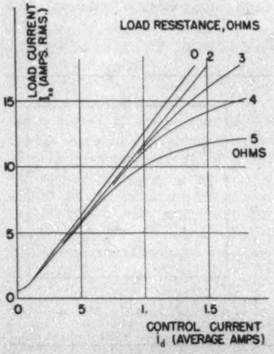

Figure 7. Control characteristics of circuit shown in Figure 5

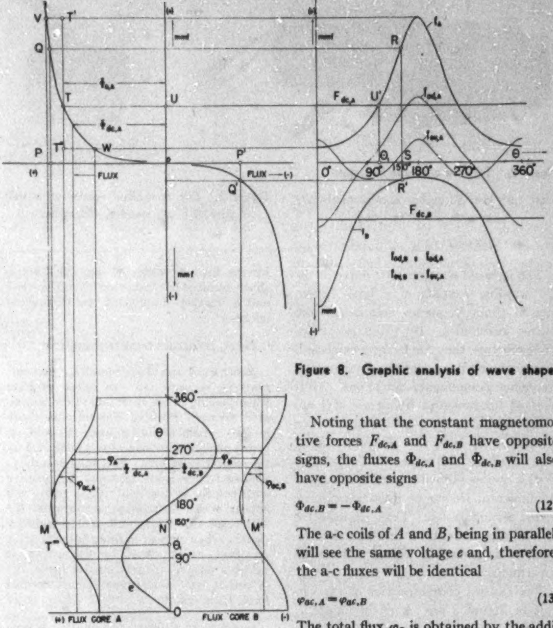

Figure 8. Graphic analysis of wave shapes

$$\frac{1}{2}(f_A+f_B) = F_{1.A}\cos\theta + F_{3.A}\cos 3\theta + \ldots = f_{od,A} \quad (9)$$

$$\frac{1}{2}(f_A-f_B) = F_{dc.A} + F_{2.A}\cos 2\theta + \ldots = F_{dc.A} + f_{ev.A} \quad (10)$$

Thus the odd harmonics, $f_{od,A}$, are the arithmetical mean between f_A and f_B. The constant term, $F_{dc,A}$, is obtained by averaging the area below curve f_A. The even harmonics, $f_{ev,A}$, follow from equation 10. The three components, $F_{dc,A}$, $f_{od,A}$, and $f_{ev,A}$, are shown in the right-hand section of Figure 8.

The current responsible for the constant magnetomotive force $F_{dc,A}$ must be produced in the d-c winding, because the a-c winding can not carry direct current during steady-state conditions. The magnitude of this current can be determined by dividing $F_{dc,A}$ by the number of turns in the d-c winding. It will be noted, Figure 5, that the same direct current also flows through the d-c winding of the *B* reactor, but in a negative direction, and

$$F_{dc,B} = -F_{dc,A} \quad (11)$$

Noting that the constant magnetomotive forces $F_{dc,A}$ and $F_{dc,B}$ have opposite signs, the fluxes $\Phi_{dc,A}$ and $\Phi_{dc,B}$ will also have opposite signs

$$\Phi_{dc,B} = -\Phi_{dc,A} \quad (12)$$

The a-c coils of *A* and *B*, being in parallel, will see the same voltage *e* and, therefore, the a-c fluxes will be identical

$$\varphi_{ac,A} = \varphi_{ac,B} \quad (13)$$

The total flux φ_B is obtained by the addition of $\Phi_{dc,B}$ and $\varphi_{ac,B}$, and is shown in the left-hand section of Figure 8. For $\theta = 150$ degrees, the total flux is now *M'N*. The required magnetomotive force *P'Q'* is obtained by the same process as *PQ*, and is plotted as a function of θ, resulting in *R'S*. Considering the symmetry of curves $\varphi_{ac,A}$ and $\varphi_{ac,B}$ with respect to the magnetization line, it will become apparent that *R'S* is one point of curve f_B, as obtained from equation 8. Hence f_B represents the magnetomotive force required by core *B*.

In terms of its own components

$$f_B = F_{dc.B} + F_{1.B}\cos\theta + F_{2.B}\cos 2\theta + F_{3.B}\cos 3\theta + \ldots \quad (14)$$

Comparing this expression with equation 8, it follows that

$$F_{dc.B} = -F_{dc.A} \quad (11)$$

$$F_{1.A} = F_{1.B} \quad F_{2.A} = -F_{2.B} \quad F_{3.A} = F_{3.B} \quad (15)$$

which means that

$$f_{od.B} = f_{od.A} \quad (16)$$

$$f_{ev.B} = -f_{ev.A} \quad (17)$$

Quiescent Flux

In the absence of an applied a-c line

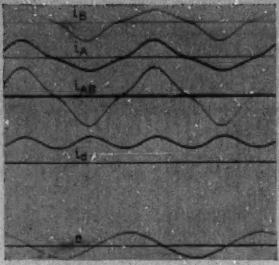

Figure 9. Oscillogram of circuit shown in Figure 5, S_D, S_B, and S closed

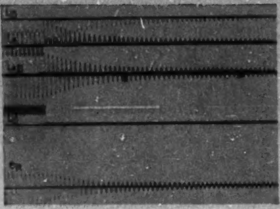

Figure 11. Oscillogram of circuit shown in Figure 5, S_B closed. S_D is closed at first. Opening S_D starts transient

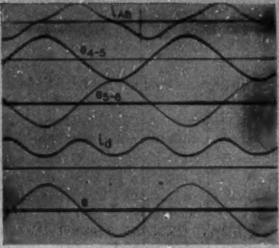

Figure 13. Oscillogram of circuit shown in Figure 6. S_D, S_B closed

voltage, the flux in core A will be $\Phi_{o,A}$ as indicated by the distance TU, obtained by intersecting $F_{dc,A}$ with the magnetization line. The flux $\Phi_{o,A}$ may be called quiescent flux, in analogy to the quiescent current in high-vacuum tubes when the grid voltage merely contains a d-c component. When steady-state a-c power is energizing the saturable reactor, the average flux $\Phi_{dc,A}$ is different from $\Phi_{o,A}$. This variation of flux has an important effect on the transient response of the saturable reactor as will be explained later. The cause of this variation can be seen as follows: the flux φ_A is obtained by operating f_A on the magnetization line. Magnetomotive force f_A consists of a constant term $F_{dc,A}$ and alternating part $f_A - F_{dc,A}$. The constant term $F_{dc,A}$ yields the quiescent flux $\Phi_{o,A}$. The effect of the alternating part is to alternately raise the flux to VT' and to lower it to WT''. The area of flux $\varphi_{dc,A}$ to the left of TT' is smaller than the area to the right of TT'', thus causing a negative flux average which lowers $\Phi_{o,A}$ to $\Phi_{dc,A}$. In high-vacuum tubes, an analogous deviation from the quiescent current takes place when an a-c grid signal is applied to the curved part of the tube characteristic; that effect is used for demodulation.

Parallel-Connected Reactors

The parallel a-c windings *X1–X2* of reactors A and B can carry currents of even and odd harmonics. The currents of even harmonics, equation 17, are in counterphase with respect to the polarity marks of the windings *X1–X2*, and, therefore, make no contribution to the total current, i_{AB}, Figure 5. The load current, i_{AB}, therefore contains odd harmonics only.

Suppose the control winding is energized through switches S_D and S_B. The resistance R_P is of very small value, in order to make the power supply a low-impedance source as seen from the terminals *Y1* of the d-c windings. Currents of odd harmonics cannot flow in the d-c windings, because the odd harmonics are in phase, equation 16, and the d-c windings are connected to each other with opposing polarity. For a similar reason, even harmonic currents, equation 17, are capable of flowing in the d-c winding. Thus the magnetomotive forces of even order can be produced by currents in the d-c windings, as well as by currents in the a-c windings. The partition of even-harmonic currents between a-c and d-c winding depends on the resistance and leakage reactance of the windings. Figure 9 illustrates this case. In this illustration the line voltage is e. The load current i_{AB} shows harmonics of odd order only. The d-c control current i_d exhibits considerable even harmonics, of which the second harmonic is most pronounced. Currents i_A and i_B show harmonics of odd and even order. Good coincidence is obtained between i_{AB}, i_d of the oscillogram, and the corresponding theoretical curves $f_{od,A}$ and $f_{ev,A}$ of Figure 8.

If a large inductance L is connected in the d-c circuit by closing switch S_L, and and switch S_D is opened, the flow of even-harmonic currents is impeded in the d-c circuit; therefore the a-c winding must carry the currents of even harmonics. Figure 10 shows this case. The wave shape of the total current i_{AB} is unaffected. The d-c control current i_d is nearly constant, and the voltage e_L appears across the inductor L. Currents i_A and i_B now carry practically all even harmonics in addition to the odd harmonics. Good coincidence is again obtained between the

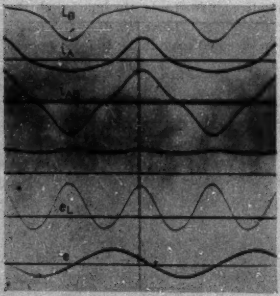

Figure 10. Oscillogram similar to Figure 9, except S_L closed and S_D open

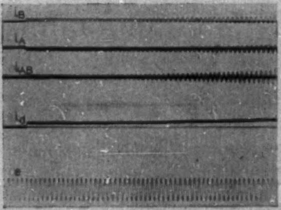

Figure 12. Oscillogram of circuit shown in Figure 5. S_B closed. Closing S_D starts transient

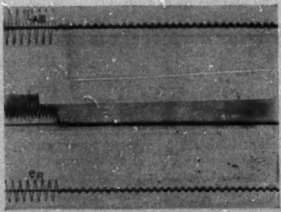

Figure 14. Oscillogram of circuit shown in Figure 6. S_B closed. S_D closed at first. Opening S_D starts transient

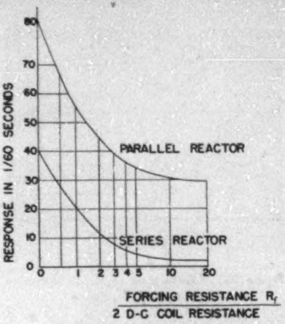

Figure 15. Transient response of parallel and series reactors

wave shapes of i_A and i_B of the oscillogram, and the theoretical curve, $f_A - F_{dc,A}$, in Figure 8.

The speed of response to a variation of control voltage, E_c, can be increased by placing a forcing resistor R_f in series with the d-c winding (S_R closed, S_D and S_L open). There is, however, a limitation to this speed-up. For a given line voltage, a change of impedance of the saturable reactor can be effected only by changing the average flux $\Phi_{dc,A}$ and $\Phi_{dc,B}$. This flux, however, can maintain constant flux linkages[11] through the a-c winding, even if the d-c circuit is interrupted; therefore, the fluxes $\Phi_{dc,A}$ and $\Phi_{dc,B}$ will not vanish instantly. If i_d is interrupted, transient currents will appear in the a-c coils. These currents will flow in a positive sense in reactor A, and in a negative sense in reactor B, thus forming a current circulating within the two reactors. Figure 11 shows the transient response of parallel-connected saturable reactors where the direct current i_d was suddenly interrupted by opening switch S_D. It can be seen that i_A immediately acquired a positive transient, whereas i_B exhibits a negative transient. As a result, the magnetic flux decays with the time constant of the a-c winding, and the change of impedance is manifested by the slowly decaying load current i_{AB}. With a load resistor R connected in series with the reactors (switch S open), the voltage across R is shown by e_R.

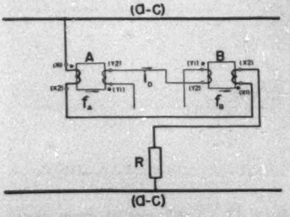

Figure 16. Arrangement similar to Figure 5 or Figure 6, except core *B* turned 180 degrees

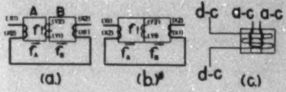

Figure 17. (a) Two cores using common control winding; (b) 3-leg core; (c) 4-leg core

Closing switch S_D will cause an abrupt start of i_d in the control winding, Figure 12, despite the large self-inductance of the control winding. The explanation[12] again lies in transient currents circulating between the a-c windings of the two reactors, maintaining constant flux linkage at the instant of switch closure. Figure 12 shows a negative transient of current i_A and a positive transient of current i_B. While the currents i_A, i_B, and i_d show abrupt changes, it is important to realize that the magnetic flux $\Phi_{dc,A}$ and $\Phi_{dc,B}$ will change only gradually, as evidenced by the slow increase in load current i_{AB}.

Series Reactor

Assume again that switch S, Figure 6, is closed. The a-c coils, being in series, make $i_A \equiv i_B \equiv i_{AB}$. No currents of even harmonics can flow in the a-c windings because such currents would have to be in phase opposition, equation 17, and the series connection between the a-c windings causes opposition of the two currents. Hence the a-c windings and the load current contain odd harmonics only. All even harmonics are flowing in the d-c winding, the d-c supply being connected by closing switches S_B and S_D. Figure 13 shows current i_{AB} as consisting of odd harmonics only. The control current i_d contains all even harmonics, of which the second harmonic is the most pronounced; e is the supply voltage for the saturable reactors. The series-connected saturable reactors can be used as a source of double-frequency power[13] by connecting a load in series with the d-c winding. In parallel-connected reactors, the even harmonics are forced into the a-c windings when their flow is impeded in the d-c winding, as previously explained. In the series-connected reactors, the a-c winding cannot carry even harmonics, and, therefore, such harmonics must appear in the d-c winding of the reactor.

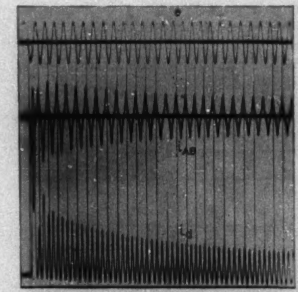

Figure 18. Oscillogram of circuit shown in Figure 6. Alternating current closed near phase angle where $i_{AB}=0$ during steady state

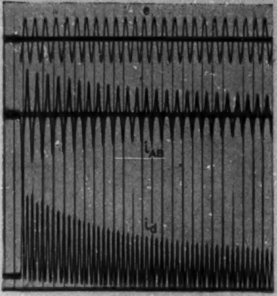

Figure 19. Oscillogram similar to Figure 18, except alternating current closed near phase angle where i_{AB} is maximum during steady state

If the flux $\Phi_{o,A}$ increases and flux $\Phi_{o,B}$ decreases (or vice versa) at the same rate, electromotive forces are induced in the a-c windings. These electromotive forces are of equal magnitude and of opposite

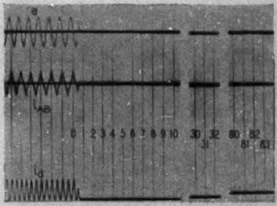

Figure 20. Oscillogram of circuit shown in Figure 6. Alternating current interrupted

polarity, and hence cannot cause a current to sustain constant flux linkages. The fluxes $\Phi_{o,A}, \Phi_{o,B}$ and hence the impedance of the saturable reactors, thus can be forced by the d-c ampere-turns. If, for instance, switch S_D is opened, the field collapses instantly, and the impedance of the reactor also changes instantly, as shown in Figure 14. When the control current i_d is interrupted, the load current i_{AB} declines immediately. In this case, switch S is open, and e_R is the voltage across the load resistance. It can be seen that the series-connected saturable reactor is capable of rapid response.

Comparison of Speed of Response

A comparison of response between the parallel and series reactor is shown in Figure 15. Circuits used are shown in Figures 5 and 6; switch S_B is permanently closed, switch S is kept open, and switching is done by S_B.

The response time is defined as the amount of time required for the peak value of the load current, i_{AB}, to pass through 0.63 (equals $1-1/\epsilon$) of the interval controlled by i_d. For a linear circuit this response time is usually called the "time constant."[14] The response times are shown as a function of "forcing," which is expressed as the ratio between the forcing resistance, R_f, and the resistance of both d-c windings. The curves show "turn-off" response from full-load current to minimum-load current. The "turn-on" response is similar.

Reactors with Common Control Winding

Suppose the electric connections of Figure 6 remain unchanged but reactor B is turned in space by 180 degrees, Figure 16. Considering the leg bearing the d-c winding, it can be seen that the magnetomotive forces $F_{dc,A}$ and $F_{dc,B}$ have the same direction in space. The even harmonics have the same direction in space as well, equation 17. Conversely, the magnetomotive forces of odd order have opposite directions in space, equation 16. If the two iron cores are now brought together, but an air gap left between the adjacent sides of the two reactors, and a common d-c winding placed around the adjacent legs, Figure 17a, the magnetic conditions in the cores will remain essentially the same. As far as the d-c coil is concerned, no odd-order voltage will be induced, because the odd-order fluxes in the two adjacent legs are of opposite phase. This is an advantage over the arrangements shown in Figures 5 and 6. While it is true that in Figures 5 and 6 the odd-order harmonics are cancelling at terminals *4* and *6*, these voltages nevertheless exist in each winding and may cause problems of over-voltage.

An important feature of this core arrangement is the existence of flux of fundamental frequency in the adjacent legs. If the control current is varied in opposite directions, residual magnetism causes the control characteristics, Figure 7, to shift. Also, if the control current i_d is turned off completely, residual magnetism would remain in the core surrounded by the d-c coil, and would prevent the magnetic amplifier from assuming its zero control-current position if it were not for the demagnetizing effect of the magnetomotive forces of fundamental frequency acting in the core. Such a core is shown in Figure 3.

Where residual magnetism is inconsequential, the two adjacent legs can be merged and a 3-leg reactor results, Figure 17b. The center leg carries a flux containing only the constant and even-order terms.

Another core construction is a 4-leg core, Figure 17c, where the two a-c windings are wound on the inner legs and the d-c winding is surrounding both a-c windings. While the basic function is the same as that of the 3-leg reactor, the 4-leg type has the advantage of smaller leakage reactance, and higher impedance with no d-c excitation. Such reactors are shown in Figure 2.

Transients

During the operation of saturable reactors, transient currents will be observed in the control windings: when the load current i_{AB} increases, the control current i_d will increase transiently, and vice versa.

Such a case is shown in Figure 18. This oscillogram was taken from the circuit of Figure 6, with S_D,S_B closed, and S open. At the start the a-c source was disconnected, $e=0$, $i_{AB}=0$, and only the control current i_d is flowing in the circuit. Near the crest value of e, the highly inductive a-c circuit was switched in. Two phenomena will be observed: the amplitude of i_{AB} is larger at the start and gradually decays to its steady-state value; secondly, the d-c component of the control current i_d rises very sharply, as evidenced by the average of i_d; this d-c transient gradually subsides, and during steady-state operation the average of the i_d-wave equals the value of i_d before the a-c source has been switched in. If the a-c source had been switched in at an instant essentially different from its crest value, additional d-c transients would be caused.[15] Such a case is shown in Figure 19.

The case where the load current i_{AB} is turned off is shown in Figure 20. The control current i_d contains, as usual, large even-order harmonic currents; the d-c component of i_d is obtained by averaging i_d. Then the load current i_{AB} was suddenly reduced to zero by opening the a-c circuit. It will be seen from Figure 20 that the d-c component of i_d suddenly drops to a very small value. Subsequently i_d increases gradually until it reaches, after approximately 80 cycles, the same value it had before the load current i_{AB} was cut out.

Both phenomena can be explained by the shift of the average magnetic flux, $\Phi_{dc,A}$ and $\Phi_{dc,B}$. Suppose that the a-c energization is interrupted at $\theta=90$ electrical degrees. The flux φ_A at this instant equals $\Phi_{dc,A}$. Due to the absence of alternating current, the magnetic flux will assume its quiescent value $\Phi_{o,A}$, which is larger than $\Phi_{dc,A}$. In reactor B the average flux, $\Phi_{dc,B}$ also is changing toward $\Phi_{o,B}$. This flux change is in the opposite direction to the flux change in reactor A. The voltages induced in the d-c windings, therefore, have opposite directions. However, the d-c windings are connected in opposition, hence the induced voltages are supporting each other. According to Lenz' law,[16] flux changes cause electromotive forces in the d-c windings, opposing the change. Hence the transient current caused by these electromotive forces will cause a temporary reduction of the direct current.

If the a-c power is increased, the direct-current will exhibit a transient increase. It is also important to note, however, that the change from $\Phi_{dc,A}$ to $\Phi_{o,A}$ cannot occur in zero time. The saturable reactor first will display a lower impedance which gradually will approach a higher steady-state value. As a result, the load current will display a larger magnitude at the beginning and will approach slowly its steady-state value.

Symbols

E = supply voltage, in rms volts
e = instantaneous value of supply voltage, in volts
$F_{1,A}$, $F_{1,B}$ = amplitude of fundamental component of f_A or f_B respectively
$F_{2,A}$, $F_{2,B}$ = amplitude of second harmonic of f_A or f_B respectively
$F_{3,A}$, $F_{3,B}$ = amplitude of third harmonic of f_A or f_B respectively
$F_{dc,A}$, $F_{dc,B}$ = constant part of magnetomotive force in core A or B respectively, in ampere-turns

f_A, f_B = instantaneous value of magnetomotive force in core A or B respectively, in ampere-turns
$f_{ev,A}$, $f_{ev,B}$ = instantaneous value of even-order harmonics of f_A or f_B respectively
$f_{od,A}$, $f_{od,B}$ = instantaneous value of odd-order harmonics of f_A or f_B respectively
I_{AB} = current in load, in rms amperes
i_{AB} = instantaneous value of alternating current in load, in amperes
i_A, i_B = instantaneous value of alternating current in reactor A or B respectively, in amperes
i_d = instantaneous value of control current, in amperes
N = number of turns of a-c winding, per reactor
t = time, seconds
ϵ = base natural logarithm, 2.718
θ = phase angle of time vector, in radians or degrees
$\Phi_{0,A}$, $\Phi_{0,B}$ = quiescent flux, in core A or B respectively, in maxwells
Φ_{dc} = constant part of φ, in maxwells
Φ_{ac} = peak value of a-c component of φ, in maxwells
φ = instantaneous value of core flux, in maxwells
φ_{ac} = instantaneous value of a-c component of φ, in maxwells
φ_A, φ_B = instantaneous value of core flux in core A or B respectively, in maxwells
$\varphi_{ac,A}\varphi_{ac,B} = \varphi_{ac}$ in core A or B respectively
ω = angular velocity of time vector, radians per second

Discussion

Walter C. Johnson (Princeton University, Princeton, N. J.): H. F. Storm is to be commended for his clear and careful analysis of the operation of the saturable reactor. He has covered a wide range of phenomena in a manner which is very helpful.

The paper brings out clearly an important point which often is overlooked, namely, that the actual d-c flux in the reactor does not correspond with the intersection of the d-c magnetomotive force with the magnetization curve, but is considerably lower under operating conditions. This must be expected in a nonlinear circuit, and, as Storm points out, it is analogous to the deviation in direct current which occurs in a vacuum-tube circuit when the tubes are operated over a nonlinear portion of their characteristics. The effect is of major importance in the saturable reactor. To give a specific example:

For a particular reactor with a silicon-steel core, when operated in the middle of its normal range, the value of required control current is about 14 times what it would be if this demagnetizing action did not occur.

The effect increases with the nonlinearity of the magnetization curve, and explains why core materials with a sharp-breaking characteristic fail to produce results as spectacular as might be expected.

As the a-c voltage increases in amplitude, the alternating flux traverses a greater portion of the nonlinear magnetization curve, and the demagnetizing effect becomes increasingly severe. As a result, the d-c flux is reduced, and the alternating current changes by only a small amount. This, of course, is the basis for the application of the saturable reactor as a constant-current regulator.

For the reactor mentioned previously, when operating in the middle of its normal range, a doubled a-c voltage increases the rms alternating current by about 25 per cent, and increases the average alternating current by only about 9 per cent. The effect is more pronounced in reactors which have a very sharp-breaking magnetization curve. The demagnetizing effect is an overruling factor in the performance of the saturable reactor; its importance hardly can be overemphasized.

Rubber Insulators for Pole Lines

H. H. WHEELER
NONMEMBER AIEE

W. F. MARKLEY
NONMEMBER AIEE

LIKE SO MANY modern developments, the use of rubber insulators on pole lines is the unexpected outcome of research originally started in a somewhat different direction. Observations over many years had shown that substantial sums were spent annually in replacing glass insulators mischievously broken, and that such breakage was confined largely to specific and well-recognized locations which seemed especially to lure children or hunters to destructive activities; sometimes one or two poles in a particular area required insulator replacements almost weekly. Figure 1 shows an example of such mischievous breakage.

In the initial consideration of this problem, some thought was given to the idea of improving the glass itself, that is, making the insulator from tempered or shatterproof glass in order to improve its resistance to breakage, but it was found that such a design was impracticable. Thought was given also to the idea of surrounding the glass petticoat with an outer metallic skirt. Although this attachment gave a surprising degree of protection, it was not entirely satisfactory.

The next device that was tried was a moulded-rubber shroud over a small glass insulator of the pony type. This too developed a satisfactory degree of protection against blows, but was rather costly because of the volume of rubber required. It became obvious at this point that the real solution of the problem was to make the insulator itself of rubber. Although it was believed at the time that a suitable rubber compound could be developed possessing adequate physical characteristics and insulating properties, there was some question as to whether any such compound would have a useful life outdoors of more than three or four years.

Mechanically, the rubber composition had to be strong enough to carry the load of a telephone or telegraph wire, and yet be sufficiently resilient so as not to crack when struck. It was also important that the insulator maintain its resilience and not crack or check for a reasonable period when subjected to the heat and ultraviolet rays of the sun.

Considering electrical qualities, surface leakage obviously accounted for so large a fraction of the current losses that high volumetric resistivity of the material was not a necessary requirement. In a dry atmosphere, the surface leakage over any insulator is negligible, but in the presence of moisture two major conditions affect leakage. The first is the specific heat conductance of the material, or in popular expression, whether it feels cold or warm to the touch. On good heat conductors, water precipitates out of the atmosphere more freely and at smaller temperature differences than on poor heat conductors. The other condition has to do with the interfacial tension between water and the insulator surface, or more popularly, whether or not water "wets" the surface. A small quantity of water on a surface with which it has a high interfacial tension, tends to draw itself up into a series of discrete globules, not touching each other and with dry surfaces between. Such a condition is conducive to low electrical leakage over the surface. If, however, the interfacial tension is low, the water "wets" the surface, and it tends to spread out in a more or less continuous film over considerable areas. This gives rise to high electric leakage.

It was found that almost any rubber composition had an adequately low factor of heat conductance, but that extremely few compounds possessed the required inherent "nonwetting" surface characteristic desired for good insulating efficiency under conditions of rain or heavy fog.

Ultimately, a vulcanized rubber compound was developed having a reasonably satisfactory combination of essential qualities. This rubber compound was of the wax-bearing type, and the composition and extent of the wax ingredient and the technique of compounding were important characteristics in its manufacture. The wax component of the mixture blooms, or migrates to the surface, continuously for years, thereby maintaining in service high interfacial tension with water and insuring the desired "nonwetting" characteristic of the insulator. In addition, reasonable self-cleaning characteristics are afforded, as is almost complete freedom from surface checking under prolonged sun exposure. This wax component of the rubber compound represents one of the principal features of Western Union patents covering the product.

Two styles of single-petticoat rubber insulators, designated as types *R-1* and *R-2*, were designed for force-fit mounting on the spindle of a steel pin. A field trial of the *R-1* insulators showed the desirability of reinforcing the wire groove. Laboratory studies of the *R-2* insulator, which was designed to contain a minimum amount of rubber, indicated that the reduction in size was carried too far. The

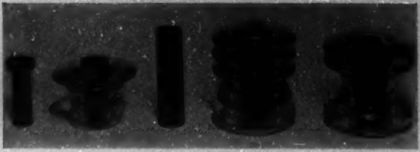

Figure 3. Rubber bushings

Left to right:
RB-1 flange-type rubber bushing
RB-1 rubber bushing in position in glass insulator, used on Case span-type transposition bracket
RB-2 straight-type rubber bushing
RB-2 bushing in position in dead-ending glass insulator
RB-2 bushing in position in power insulator

essential details of these two designs were combined in a third design, called type *R-3*, which is now standard for use with steel pins. A fourth design was tried, moulded so as to provide an inner petticoat, but moulding difficulties were encountered which made the cost of manufacture prohibitive.

The design of the type-*R-3* insulator is shown in Figure 2, along with other styles of rubber insulators that subsequently were developed for specific purposes. The type-*R-4* insulator shown was designed with an inner thread for use on wood pins, and currently is being employed in considerable quantities in the telephone industry. The type-*R-5* insulator, designed for use on telephone-type, short-shank transposition pin, was developed to meet requirements of two Canadian railroads. The type-*RC-1* insulator was designed for use on the Case span-type transposition bracket where the expense of replacing a broken glass insulator is sometimes prohibitive. The compound used in the type-*R-5* and type-*RC-1* insulators had to be modified somewhat to improve its toughness, to enable the insulators to withstand the continuous severe stresses encountered in service.

This latter compound was adapted subsequently for use as bushings in various types of glass insulators, as shown in Figure 3. It was found that this rubber composition not only provided adequate resilience for the assembly, but materially improved its over-all electrical efficiency The *RB-1* flange-type rubber bushing shown was designed for use with the glass insulator on the Case span-type transposition bracket. The *RB-2* straight-type rubber bushing was designed for the shackle-type glass insulator to replace the lead bushing which normally was used, but which was not entirely satisfactory. The *RB-2* bushing also is shown in position in a glass insulator for use in power work; this combination of rubber bushing and glass insulator is being used to replace porcelain insulators, and is an entirely new development in the power industry.

Rubber insulators moulded with these approved compositions definitely have solved the breakage problem, not only in service but also in shipping and handling. In actual tests, with insulators mounted on steel pins, loads that resulted in bending the pins left the rubber insulators unmarked. One such insulator, dropped from a 12-story window to the concrete pavement, was entirely unaffected. Bullets would pass through, but would not shatter the insulators. The smaller projected area made hits less likely, and the lack of any visible evidence on the insulator when struck discouraged its use as a target for marksmen.

The first extensive field installations of rubber insulators on steel pins were made in 1939 and 1940 in a wide variety of areas including Florida, representing severe sunlight exposure; the West Coast along San Francisco Bay, representing a difficult fog area; Nebraska, representing a heavy wind exposure; and the New York-Philadelphia area, representing a wide diversity of weather conditions, varying from dry to fog and heavy rains. Numerous small installations also were made in locations where the breakage of glass insulators was a major consideration.

After six years of service, a number of these insulators were removed from the various areas for rigorous laboratory inspection. It was observed generally that the insulators were practically as good as new, except those from the Florida area, which showed a slight superficial checking of the rubber. All of these insulators continued to maintain their original toughness and elasticity, as well as their self-cleaning and water-repellent characteristics.

In the heavy wind exposure in Nebraska, it was found that the rubber insulators are capable of satisfactorily supporting the relatively heavy loads resulting from large-gauge iron wires. Where the rubber insulators supported number 9 copper wire in this area, the resilience of the rubber materially reduced tie-wire breakage, and resulted in fewer fatigue breaks of the line wire.

In the New York-Philadelphia and the West Coast areas, the rubber insulators at critical points of support, such as at corners and terminals, showed no weakening under the severe mechanical strain encountered.

Because the line sections most vulnerable to insulator damage were selected initially for rubber insulator installations, the field reports indicated that the saving in broken glass insulators for the first year more than paid for the rubber insulators, and resulted in reduced material and labor costs. In addition, by eliminating the broken insulators which ordinarily caused increased leakage and wire trouble in wet weather, sustained line insulation was achieved, with consequent increased operating efficiency of the circuits.

The electrical performance of rubber insulators in the various classes of service has exceeded original expectations considerably. Relative insulation-resistance characteristics, determined from d-c leakage measurements on circuits insulated with rubber and with glass, respectively, are shown by the curves in Figure 4.

In Figure 4, the curves representing Elizabeth–Trenton circuits, comprising about 45 miles of open wire (approximately 3,100 insulators per circuit), indicate the average performance, during periods of heavy rain, of two rubber-insulated circuits and two glass-insulated circuits, all installed at the same time, as compared with old glass-insulated circuits that have been in service for 30 years or more.

These curves show that, after the first few months, the rubber-insulated circuits develop and maintain about a 100 per cent improvement over old glass-insulated circuits in insulating properties. On the other hand, while the new glass-insulated circuits appear to be nearly five times as good as the old glass-insulated circuits, and almost twice as good as the rubber-insulated circuits in the early stages of exposure, they deteriorate more rapidly in insulation resistance, so that after the first three or four years on the line, they approach the rubber-insulated circuits in insulating characteristics, and maintain this equivalent electrical performance on further exposure. Although these curves reveal that the circuits insulated with rubber and new glass maintain, on prolonged exposure, a two-to-one superiority over old glass-insulated circuits, field reports show no noticeable difference, under normal weather conditions, in the operating performance of any of these circuits, indicating that the old glass insulators still possess adequate insulation.

In Figure 4, the curve representing Pacific Coast circuits along San Francisco Bay, comprising about 22 miles of open wire (approximately 900 insulators per circuit), shows the average performance of two rubber-insulated circuits as compared with old glass-insulated circuits that have been in service for 30 years or more; no new glass-insulated circuits were erected in this section when the rubber insulators were installed. This curve indicates that, during periods of widespread fog, the rubber-insulated circuits during the first two years of service are 8 to 20 times as good as the old glass-insulated circuits from the standpoint of insulation resistance. The rubber-insulated circuits then reach a state of equilibrium, in which they appear to maintain a line insulation practically four times as good as old glass-insulated circuits. This relative performance is confirmed also by current field reports, which indicate that during periods of adverse weather, when all of the glass-insulated circuits are completely "fog-bound," the rubber-insulated circuits provide reasonably satisfactory operation.

These relatively extensive field tests with the steel-pin-type rubber insulators indicate generally that in normal telegraph service, the electrical efficiency of rubber-insulated circuits in heavy rain exposure can be expected to be about on a par with that of glass-insulated circuits of the same age, and superior to glass-insulated circuits in an area where heavy fog and high humidity are encountered. Similar results have been reported on the use of the wood-pin-type rubber insulators by the telephone industry.

Although no carrier circuits have been insulated as yet exclusively with rubber, short sections have been so equipped, with no apparent change in operating efficiency. Limited laboratory studies on the relative transmission efficiency of rubber- and glass-insulated circuits at various frequencies indicate that the a-c wet weather losses for both types of circuits are about the same for frequencies up to, and somewhat beyond, 30 kc. Because of limited experience with rubber insulators at frequencies appreciably higher than 30 kc, and because of the fact that at these frequencies electric losses mount rapidly, it is not possible to say at this time whether a circuit insulated entirely with rubber in this higher frequency range would provide acceptable operating efficiency, but it is believed that a small percentage of rubber insulators in such a circuit would not adversely affect its over-all transmission characteristics.

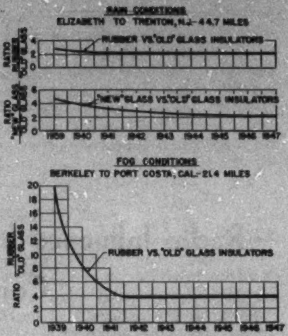

Figure 4. Relative insulation resistance of open-wire circuits

Rubber insulators never will equal in lasting qualities the more fortunate glass insulators, many of which, in their 50 or more years of existence, have outlasted not only the original crossarm on which they were mounted, but also its replacement. However, it is anticipated that the average life expectancy of rubber insulators will be 15 years or more, judging from their performance during the past nine years. Furthermore, their outstanding record of durability and over-all electrical and mechanical efficiency during these nine years warrants their continued use, even if it were not for the determining factor—that rubber insulators are, without question, the answer to the problem of mischievous breakage.

Radio Influence from High-Voltage Corona

GORDON R. SLEMON
ASSOCIATE AIEE

IN THE study of high-voltage power transmission, corona phenomena have received considerable attention. The power loss which accompanies corona has been investigated to the extent that general prediction may be made under most conditions. The increase in the voltage level of long-distance transmission lines, coupled with the extension of communication facilities, has created a demand for a more adequate knowledge of the radio-frequency propagations which may be expected from corona.

The experimental work of this project has been directed toward two main objectives. The first of these is a clarification and extension of the basic concepts of the space-charge phenomena which occur in corona. The general conditions under which radiating impulse currents will occur have been described, and an attempt has been made to show the effects of some of the variable factors. From the observations, certain additions and clarifications have been made in corona theory. With the aid of this firmer theoretical background, a beginning has been made in the field of radio-interference control under various voltage conditions.

Equipment

Because of the sensitive nature of the field measurements necessary in this corona study, the equipment was installed in a radio-frequency-shielded cage. This cage was ten feet square, eight feet high, and of standard construction with wire mesh on both inner and outer walls.

POWER SUPPLY

Supplies of 25, 60, and 500 cycles per second power, all at 110 volts, were brought into the cage through radio-frequency suppressors. Transformers were installed to supply continuously-variable voltages up to 50 kv at all three frequencies.

CONDUCTOR-PLANE CONFIGURATION

Separation of the effects of positive- and negative-potential corona discharges was accomplished by the use of a single conductor mounted parallel to a grounded plane. The electric field produced about this conductor is identical with that about one conductor of a 2-conductor, single-phase transmission line with double the conductor-to-plane spacing and operating at double the voltage.

The plane consisted of aluminum sheets connected mechanically and electrically to one wall of the cage. Bakelite post insulators were attached on a slide arrangement to the two adjacent walls. Most of the tests were made on a number 8 smooth solid conductor as this was the largest diameter which the 50-kv power supply would allow.

BRIDGE FOR CORONA CURRENT MEASUREMENTS

To separate the corona current from the capacitive charging current of the conductor, a simple capacitance-resistance bridge, Figure 1, was constructed using the conductor plane as one capacitance arm.[1] The bridge was balanced at a voltage below corona threshold. Above the threshold voltage, the detector voltage is a measure of the corona current.

MEASURING EQUIPMENT

High- and low-frequency radio noise meters were used for comparative measurements of the corona radio noise. Inside the cage, the induction field predominates. As there was some doubt of the accuracy of a rod-antenna instrument in this field,[2] no quantitative measurements of radio noise were made.

A communications receiver was fitted with a probe antenna for use in radio-noise location. For measurement of the intensity and phase of the audible corona discharge, a sound-level meter with microphone was employed. Also, it was thought advisable to analyse the visible spectrum radiations from corona. The output of a photoelectric cell was amplified with provision for differentiation, in order that constant and pulse radiations might be separated.

The outputs of all measuring devices could be applied to the plates of a double-beam oscilloscope for comparison.

A-C Corona Characteristics

The first set of tests were concerned with the corona characteristics of alternating voltage on a smooth, polished conductor. This surface does not represent a practical condition for service conductors but does eliminate a number of intangible factors. Later in the study, surface contaminations are reintroduced.

CORONA THRESHOLD VOLTAGE

To cause ionization of atoms by a single electron collision, a certain critical voltage gradient is required throughout the mean free path of the electron. This gradient is a function of the gas ionization potential and of the gas density. For air, the gradient required at the surface of a conductor of radius (r) is given in Peek's formula[3]

$$g_e = 29.8(K)\left(1+\frac{0.301}{\sqrt{K\cdot r}}\right) \text{ kv per centimeter}$$

where

$K = 3.92b/(273+t)$
b = pressure in millimeters of mercury
t = temperature in degrees centigrade

Paper 49-60, recommended by the AIEE communication committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted June 17, 1948; made available for printing December 28, 1948.

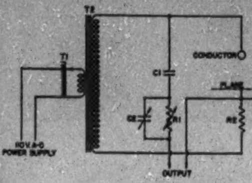

Figure 1. High-voltage circuit for corona current measurements

C1—20-micromicrofarad 50-kv parallel-plate air capacitor
C2—Variable capacitor to balance out residuals
R1—Variable resistance to balance capacitance-resistance bridge
R2—Fixed resistance in capacitance-resistance bridge
T1—Variac. Primary: 110 volts, 25 to 500 cycles per second. Secondary: 0 to 135 volts
T2—High-voltage transformer. Primary: 110 volts. Secondary: 50,000 volts

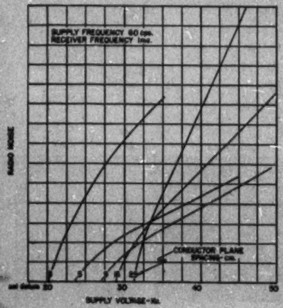
The voltage which will produce this surface ionizing gradient has been calculated as

$$e_c = g_c' r \frac{\left(\frac{s}{r}-1\right)}{\left(\frac{s}{r}+1\right)} \cosh^{-1}\frac{s}{r} \text{ kv peak}$$

where s is the spacing from the conductor center to the plane in centimeters.

The corona threshold voltage was observed experimentally by radio interference, audible noise, and visible light. All three propagations were initiated at the same voltages; this voltage corresponded closely in all cases to the critical corona voltage calculated above. The corona threshold was found to be independent of the frequency of the supply voltage over the range studied. The voltage of corona initiation with increasing voltage was found to coincide with that of corona extinction on decreasing voltage.

Figure 2. Radio noise versus supply voltage with various conductor-to-plate spacings



RADIO NOISE

Figure 2 shows a typical set of curves of radio noise with supply voltage as the independent variable. It is noted that the curves are very nearly linear, with the exception of the low intensity portion which has a greater slope. This would indicate that the magnitude of the radio noise from a smooth conductor is roughly proportional to the increase of the applied voltage over the threshold value.

In Figure 2 it is noted that the minimum slope occurs for the 5 to 9 centimeter region of spacing. In Figure 3 the same results are replotted on an abscissa of spacing. These curves indicate that, if radio noise is to be allowed, there appears to be an optimum spacing which will produce the lowest value of noise for a particular voltage. Since the amplitude of propagated radio noise is dependent on the complex factors of conduction and absorption of corona energy, there might be doubt as to the applicability of the conductor-plane results to a transmission line. There is some confirmation of possible analogy in this factor in the work of H. L. Rorden.[4] In his work on a 220-kv transmission line, he found that the radio noise at a short distance perpendicular to the line could be reduced by about half by a reduction in conductor flat spacing from 27 feet to 18 feet.

As to the relative intensities of radio noise over the radio-frequency spectrum, a reduction in noise intensity with increase in receiver frequency was noted in all cases.

PHASE ANALYSIS

The audio output of the radio noise meter and a voltage in phase with the supply voltage were applied to the vertical plates of a double-beam oscilloscope, Figure 4. It is observed that radio noise is produced, in this smooth-conductor case, only in the region of voltage about the negative peak of the wave. In the range of voltage up to double the threshold value, no radio noise occurred in the positive half-cycle.

The audio output of the meter appears as a series of random pulses of almost equal amplitude phased in a clearly defined group. As the voltage is increased above threshold, the phase width of the group increases; the amplitude of the group, however, remains almost constant. Accurate measurement of the phase limits of the group showed that the radio noise for the lower supply frequencies occurs only during that portion of the negative wave for which the voltage is in excess of the threshold value. Using a 500 cycle per second supply, the phase of corona initiation was advanced from 5 to 10 degrees beyond the 60 cycle per second case, indicating a possibility of residual ionization effect.

CORONA CURRENT

Observation of the corona current wave showed that the positive portion of the wave was smooth. On the negative portion, current pulses were superimposed Figure 5. The lower-frequency components of the corona current were removed by a short time-constant differentiating circuit, leaving only the high-frequency, noise-producing currents shown in Figure 6. These wave forms were compared with those of receiver audio output in Figure 4; the corresponding phases of initiation and extinction have been found to be identical.

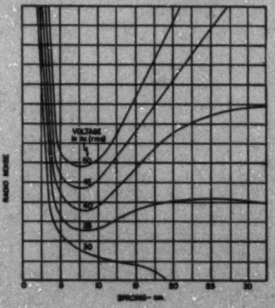
AUDIBLE NOISE

When the time delay of sound travel from the conductor to the microphone was used as a correction, it was found that the initiation phase for audible sound corresponded closely with that of radio noise. No correlation could be expected on the phase of extinction because of the sound echoes throughout the cage.

VISIBLE CORONA

Wave forms of the amplified output of a photoelectric cell focused on the conductor were observed. It was found that the visible corona in the negative voltage cycle was of a pulsating nature, and that its phase limits corresponded closely with those of radio noise. The positive-voltage

Figure 3. Radio noise versus conductor-to-plane spacing for various applied voltages



corona produced a relatively constant illumination during the ionized period.

Rectified Sine Wave-Form Characteristics

In some of the theories which have been advanced on the subject of conductor corona, the effects of residual ionization from the positive voltage cycle have been considered important in the transient phenomena noted during the negative half-cycle.[1] To analyse this interrelation, it was thought desirable to apply the positive and negative half sine waves of voltage to the conductor separately. To do this, a high-vacuum rectifier was placed in series with the high-voltage lead to the conductor.

With the positive sine wave, no radio propagation was observed up to the maximum voltage of 62.5-kv peak. The normal threshold voltage was 38.2-kv peak. The thresholds of audible and visible corona coincided with the alternating-voltage value. The nature of the audible noise was a low-amplitude, modulated hiss rather than the staccato pulse observed in alternating current. A bluish-white glow appeared about the conductor while in corona. The intensity was found to be roughly proportional to the excess of the applied voltage over threshold value.

Applying the negative sine wave of voltage, no noticeable difference was observed in the results of these tests and those made on alternating current. It would appear, then, that a theoretical analysis of corona in the negative cycle of an alternating-voltage wave will have to be based on charges produced during that negative cycle.

D-C Corona Characteristics

A study of the corona phenomena with direct current was indicated for several reasons. The effect of rate of change of voltage is eliminated from the list of variables, and direct current provides the simplest case for theoretical analysis of the phenomena which produce radio noise. Also, with the possible advent of d-c transmission, the results assume importance.

With positive direct current applied, no radio noise was radiated by the smooth, polished conductor up to double the normal ionization voltage. There was a barely-audible corona noise having the nature of a hiss, the frequency of which seemed to be dependent on voltage. A bluish-white glow appeared and was found to be unmodulated.

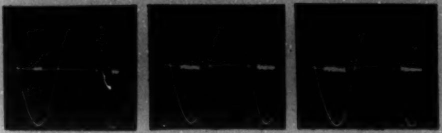


Figure 4. Radio noise from a smooth conductor at 30, 40, and 50 kv

60-cycle timing wave is in phase with supply voltage

As would be expected, radio noise was produced with negative voltage on a smooth conductor. However, the threshold of radio noise occurred at a voltage considerably higher than would be expected from the a-c tests. A typical pattern of negative d-c radio noise is shown in Figure 7. The wave form appears to be a mixture of pulses of random amplitudes and of repetition frequencies which increase with voltage increase. Actually, the interference to communications is not nearly so severe with the d-c radio noise because the continuous wave form has none of the lower harmonics of the power frequency present in a-c noise. The audio output of the receiver is a hiss which can be largely eliminated by limiting the high-frequency audio response of the receiver.

The audible noise from negative direct current shows characteristics which are almost identical with the receiver audio output. The visible corona appears as regularly spaced tufts along the conductor. These tufts are reddish in color and increase in number as the voltage is increased.

Effect of Contaminations

Up to this point in the study, all results have applied to smooth, polished conductors. To obtain a picture of what might be expected in service, contaminations were introduced.

Mutilations

As an introduction to the effect of surface roughness of conductors on corona, a single burr was produced on the conductor. This burr did not reduce the radio noise threshold. But, it is seen in Figure 8 that, while the negative-cycle radio noise remained unchanged, considerable radio noise was introduced into the positive-voltage cycle. Since this noise was caused by only one burr, positive-cycle radio noise promises to be severe on mutilated conductors.

Oil and Grease

On leaving the factory, new conductors often are coated with a film of die grease. This condition was produced on the test conductor, but no detectible change in radio-noise characteristics from those of a smooth conductor could be observed. Such was not the case, however, when irregular coatings of heavy grease were applied. With positive direct current and in the positive of the a-c cycle, corona brushes appeared, not from the projections, but from the thinly-greased areas. Radio noises occurred in the form of severe pulses, the pulse repetition frequency of which increased with increase in voltage.

Weathered Conductors

Prolonged corona on the conductor was observed to produce a surface condition similar to that of a slightly weathered conductor. Tests with this surface showed radio noise with negative direct current to be reduced by about 50 per cent in amplitude. When alternating current was applied, radio noise was produced more or less of equal magnitude in the positive and negative half-cycles, with a reduction of about 25 per cent in noise-meter reading. There is a possibility that tests on a conductor which had been fully weathered in service, would show a predominance of positive-cycle radio noise. The radio noise from newly-constructed transmission lines has been observed to reduce after the line has been in service for some time.[4] Generally, this characteristic has been explained by the fact that die grease and surface contaminations, incident to manufacture and stringing,

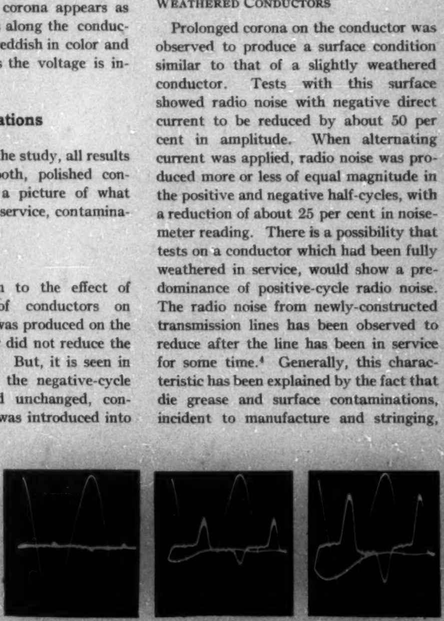

Figure 5. Corona current on a smooth conductor at 30, 40, and 50 kv

Same timing wave as in Figure 4

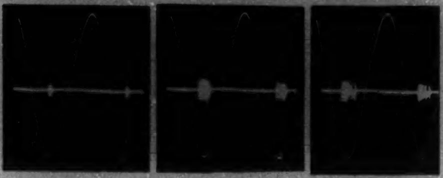

Figure 6. Radio-frequency components of the corona current shown in Figure 5

have been burned away by corona. The test observations indicate that this reduction may be effected partially by the added contaminations coincident with conductor weathering.

WATER

The severest case of corona occurs under weather conditions of rain, fog, sleet, and snow. Probably the most common and most important conductor surface contamination is, therefore, water. A fine mist of distilled water was produced about the conductor. With positive direct current, severe radio noise was initiated at about 60 per cent of the normal corona threshold voltage. When the mist cleared, leaving only the water droplets on the conductor, the radio-noise threshold voltage was increased slightly. It appeared, from the results of various tests, that water on the conductor is the important factor. Water in the surrounding dielectric caused changes, all of which were insufficient to warrant separate study. As with other contaminations the repetition frequency of the pulses increases with voltage increase, such that the most objectionable noise occurs in the low pulse repetition frequency range just above threshold voltage. With positive d-c transmission, the radio-noise threshold for a wet conductor probably would be considerably below the operating voltage, thus by-passing the most objectionable radio influence. The effect of water, however, may be the controlling factor in positive d-c work.

From previous work on contaminations, it was expected that water might have opposite effects with positive and negative direct current. It was found that, with negative direct current, water sprayed on the smooth conductor eliminated all radio noise. The radio noise did not recur until the water film was allowed to evaporate from the conductor surface. These results are substantiated by tests on transmission lines using alternating and direct voltages up to 300 kv. It was found that, for otherwise similar conditions, the ratio of positive d-c to negative d-c radio noise varied from three for fair weather conditions to about 100 for a heavy rain condition.[6]

Conductor Coatings

The effects of various conductor contaminations on radio frequency propagations have suggested the possibility of radio noise control by special conductor coatings. No attempt has been made here to develop practical coatings, but certain of the physical requirements will be indicated. The corona loss factor has not been considered in this study. It is probable that losses may be increased by the methods suggested here for radio-interference control.

POSITIVE DIRECT CURRENT

With a smooth conductor, the process of corona formation and maintenance takes place without radio-frequency radiation. When the conductor surface is contaminated or mutilated in any way, however, radio noise is produced. On all outside installations, the effect of atmospheric water is a controlling factor. Since water has a high dielectric constant and a high dielectric strength, it was doubtful if any insulating coating would be advantageous unless the insulation extended beyond the critical gradient region. A film of insulating varnish provided noise characteristics which substantiated this point.

Of the coatings tested, the only one which showed any advantage over the smooth condition was a conducting rubber. When water was sprayed on this coating, the radio-noise threshold was raised about 90 per cent above that of a smooth, wet conductor. The amplitude of the signal was comparatively low over the range above the threshold voltage. When dry, the radio noise increased until it was slightly below the value for the smooth, wet condition.

NEGATIVE DIRECT CURRENT

Radio noise with negative direct current has been shown to be most severe with a smooth, polished surface. Both insulating (water) and conducting (weathered) surfaces have tended to reduce the radiation. A carefully applied coat of varnish or enamel gave characteristics similar to those of water on the surface. Irregularities, however, produced severe radio noise.

A conducting coating of sodium chloride was applied as a saturated solution in water and allowed to crystallize. Over the greater part of the voltage range above threshold, the radio noise was reduced by over 90 per cent from its smooth value. This coating appeared to have the required structure and conductivity for radio-noise reduction. To determine the effect of water on this type of coating, a crystalline surface of dichloro-diphenyl-trichloroethane (DDT) was obtained. The reduction in radio noise was about 75 per cent from the smooth, dry condition. Water was sprayed on the conductor, and the radio noise was further reduced to about 70 per cent of the dry, coated value.

It was not certain whether the radio noise was reduced by the point structure of the coating or by its value of conductivity. Thus, a smooth coating of conducting rubber was tested with negative direct current. The radio noise was reduced by about the same percentage as for the DDT coating, but, since the audible noise was almost eliminated, the possibility arose that only a few points were producing severe radio noise. These points were isolated by detection of visible corona, but the surface could not be repaired easily. It is possible that a well-applied, pure coating of conducting rubber might have the same effect as a water film in noise reduction. Water sprayed on the imperfect rubber coating further reduced the noise to about 60 per cent of its dry, coated value.

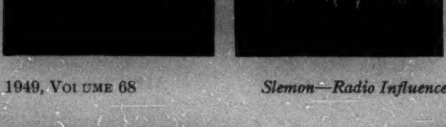

Figure 7. Radio noise from a smooth conductor with 50- and 60-kv negative direct voltage applied

Theory

The theory of ionization by collision is generally accepted as describing the process of breakdown of air under electrical stress. As the field potential gradient is increased, free electrons, present in atmosphere due to ultraviolet, cosmic, and radioactive radiations, attain a drift velocity proportional to the voltage gradient and inversely proportional to the gas density.

The general gradient and potential conditions to cause corona initiation have been discussed in the section on corona threshold voltage. There appears to be a slight difference in the voltage at which ionization is produced about positive and negative conductors. The production of space charges and the process of recombination differ widely for positive and negative conductor potentials. The cases, therefore, will be considered separately.

Positive-Potential Conductors

With positive potential on the conductor, free electrons in the surrounding region are attracted toward the conductor. As they reach the critical gradient, the ionization process establishes electron avalanches. A highly ionized region will exist about the conductor and may extend somewhat beyond the critical gradient region because of the average velocity of electrons moving inward in a field slightly lower than required for ionization. The electrons of ionization will be absorbed by the conductor. The positive ions will move outward in an ever-decreasing field such that few, if any, ionizing collisions may be accounted for by their motion. These ions provide the medium of current flow to the zero- or negative-potential plane.

The ionizing procedure is effected by a transfer of energy from the electric field to the acceleration of free electrons and, from these, to the high-energy electrons of ionization. No distinct electromagnetic radiation is produced in the process. Because of the outward motion of the ions and the process of ion neutralization by contact with negative ions, there is a continual ionization after the initial avalanche. The radiations produced throughout the ionized region by the deionization process appear to be confined to shorter wave length visual and ultraviolet bands. With a smooth conductor, no radio frequency propagation is noticeable.

This result would be expected from a study of the field configuration shown in Figure 9. The concentration of electrons passing into the conductor surface causes a reduction in surface potential. The positive-ion field increases the positive potential above the normal value at a distance from the conductor. This redistribution of the potential relieves the overstressed condition of the air; the potential gradient about the conductor is just sufficient to maintain ionization.

Negative-Potential Conductors

When negative potential is applied to the conductor, the free electrons in the immediate region are expelled and thus, are not available for continued ionization. The necessary electrons then must be emitted by the conductor. There are two probable means by which such emission could take place. The ions in the surrounding air will be accelerated toward the conductor. By bombarding the conductor surface with the energy received from the field, these positive ions may cause secondary emission. The process of secondary emission is somewhat inefficient; the number of electrons emitted is only a few per cent of the incident ions. However, only a few electrons are required to start the ionization process. The number of electrons available for ionization increases almost exponentially with distance from the conductor surface. Low-work-function surfaces would provide the best emitters in this case.

The other probable means of electron supply is field emission. Very high electrostatic fields are set up about surface irregularities, projecting crystals, and submicroscopic points. In these regions of high stress, the field energy may be sufficient to draw electrons out of the metal surface. Since the gradient at these points may be many times the average gradient, almost all the emission current is concentrated at these points. Field emission will be greatest for those surface impurities which have low work functions.

There is a certain similarity in the surface requirements for these two emission methods. Both are more efficient with low-work-function surfaces or surface impurities. Severe field accentuations about irregularities would have a greater effect on field emission than on ion bombardment.

In order to clarify the basis of certain observations, the following theory of negative corona is proposed. It is assumed that, under sufficiently high surface gradient, electrons will be emitted from the conductor surface by ion bombardment or field emission. When the potential is sufficient for ionization, electron avalanches occur outward from the conductor. These produce a positive-ion space charge, which increases exponentially with distance from the point until the potential gradient drops below ionization requirements, Figure 10(a). The positive-ion space charge causes an immediate increase in the gradient at the conductor surface with a proportional increase in emission current. The surface gradient continues to increase until the positive-ion space charge moves inward to contact the conductor. At this time, the surface potential is reduced greatly, and the gradient will drop considerably below ionization value. The ions are neutralized by contact with the conductor, giving a somewhat constant value of electron current from the conductor during this period. The space-charge distribution for this part of the cycle is shown in Figure 10(b). When the positive-ion charge is cleared, the gradient conditions are restored and electron avalanches again occur.

During this cycle, the electrons of ionization move outward into an ever-decreasing field. When their velocity is sufficiently small, negative ions are formed which drift toward the more positive potential.

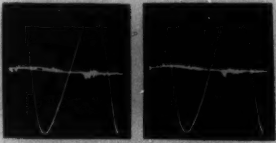

Figure 8. Radio noise with a single burr on an otherwise smooth conductor at 40 and 50 kv

Note the radio noise during the positive cycle of the voltage wave

Because of the large differences in electron and ion mobility, the period of ionization will be very short in comparison with the period of positive-ion neutralization. Thus, the corona current for each point will be a steep pulse followed by a slowly varying current of the same polarity for a period many times the pulse length.

A study of the potential distribution curve of Figure 10(b) shows that the gradient throughout the positive- and negative-ion regions is low. This increase in potential at some distance from the conductor distorts the potential-field lines in such a way as to reduce the gradient for a certain conductor length about the ionized region. Since the applied voltage determines the intensity of each electron avalanche and resultant ion cloud, only a certain discrete number of these corona tufts will exist simultaneously along the conductor length. These tufts will be spaced automatically such that they protect the intervening regions from excess gradients. The uniformity of the spacing

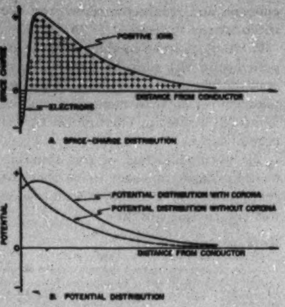

Figure 9. Field diagrams of corona from a positive-potential smooth conductor

will depend on the surface condition and the distribution of high-emissivity points on the surface. As the voltage increases, the corona tufts must be more closely spaced to cause a sufficient reduction in the field between these points.

Contaminations and Coatings—Positive Potential

We have observed that positive potential produces radio noise from a conductor only when the conductor surface is contaminated or roughened. Both insulating and conducting coatings produce similar impulse currents, but the mechanics of the discharges are somewhat different.

The effect of conducting coatings and contaminations may be explained partially by reference to Starr's work on high-voltage d-c point discharges.[6] Apparently, point discharge may be classified into three types. A sharp, slender point produces a small bead of ionization at its tip, with a tapering sheath of ionization extending back from the point. No normal radio noise accompanies this discharge. A polished conical point of about 60 degrees width produces a sharp ionized needle projecting some distance from the point and producing a harsh radio noise. The third type, a rough point or one of about 120 degrees width, has an ionized bead at the tip with a broad plume of discharge blossoms extending outward. The corona current is low; the radio noise is more regular and of higher repetition frequency.

Surface irregularities such as burrs, conducting coatings, and crystal points may be considered as separate discharge points. There will be certain mutual effects of adjacent discharges, but the theory of their radio-noise production will be similar to that of a combination of individual points. It was found that a needle point projecting from the conductor produced no radio interference. In this case, the positive space charge apparently builds up a stable equilibrium over a wide range of currents. This space charge, with its resultant effect on the potential gradient, blocks off the development of any positive streamers and hence no current impulses occur. This protective effect is similar to the case of a smooth conductor.

The mutilated or weathered surface presents many point structures which are of the second or third type. These points produce high regional gradients, and streamers composed of electron avalanches project from space toward the points The positive space charge thus created momentarily reduces the gradient and blocks further ionization until the ions have been cleared sufficiently from the point region. If the point is regular and symmetrical, a symmetrical field and charge structure will result. The discharge phenomena then should show a definite regularity. If the point is sharper as in the second type, the ion cloud produced does not provide as complete a shielding barrier. A more random discharge may be expected from these points.

The visual corona which will occur about this point-structure surface will depend upon the concentration of the points. If only a few are present, the normal bluish-white glow will exist about most of the surface. At the point, a needle or blossom corona tuft, reddish in color, will be observed. The normal glow in the surrounding region will be reduced or eliminated as a result of the tuft-gradient effect. As the points become more numerous, all corona will be concentrated at the points, and the gradients of all intermediate regions will be reduced by the projecting corona tufts. There will be a certain automatic spacing of tufts, just as in the case of negative potential.

If an insulator in the form of a water drop is placed on the conductor, a field distortion will occur. The water, being of high dielectric constant, will have a low voltage drop across it. Thus, the potential at the top of the drop is much greater than normally would exist at that distance from the conductor. As this provides the nearest and highest potential, electron avalanches will project toward this point. As the electron concentration builds up, the potential gradient through the drop increases until breakdown potential is reached. The result is a current surge into the conductor. It might be thought that breakdown would occur in the air about the drop rather than through it because of the higher dielectric strength of water. Observation, however, indicates the latter to be the general case.

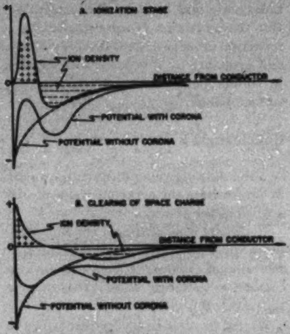

Figure 10. Space-charge distribution in negative-potential corona about a smooth conductor

Contaminations and Coatings—Negative Potential

The effect of any surface contamination will depend chiefly on two characteristics. Probably the most important factor is the increase in regional potential gradient caused by any point structure. The other factor is the electron emission characteristic of the coating. This will be controlled by the work function or ionization potential of the surface material.

There are then two possible approaches to the control of radio noise from a negative conductor. All emission may be eliminated up to a high potential by covering the surface with a smooth coating of high ionization potential. Water, which has an ionization potential of 12.56 volts, as compared with 7.68 for copper, and which also provides a smooth surface, was found to provide this effect up to a potential greater than twice the dry critical potential.

The other method of radio-noise control is exemplified by the crystalline coatings. In this case, the surface work function is intentionally lowered and the surface gradient increased. Under these conditions, the radio-noise-producing discharges are more numerous but less severe, and the advantages of lower-amplitude higher-repetition-rate pulses are obtained.

The first of these methods has certain advantages. From the radio-noise standpoint, complete elimination is naturally the more desirable. Also, the prevention of severe ionization about the conductor might result in a theoretical elimination of corona loss. With the other method, radio noise may be reduced considerably. But this reduction is accompanied by a reduction in radio-noise threshold voltage, and probably by a considerable increase in corona power loss over the smooth-surface value.

Conclusions

The following general conclusions may be drawn from the experimental work described in the preceding text:

1. There is an optimum conductor-to-plane spacing which will produce the lowest value of radio noise from corona on a conductor operating at a voltage above the corona threshold voltage.

2. An increase in the frequency of the supply voltage causes an increase in the magnitude of the radio noise, except at conductor spacings lower than the optimum value. The radio-noise threshold is independent of supply frequency.

3. Radio noise from corona on a smooth conductor is produced only during the negative peak of the applied voltage wave. The radio noise occurs within the time during which the negative voltage exceeds the corona threshold voltage for the lower power frequencies. An advance in the phase of radio-noise initiation was observed for supply frequencies of about 500 cycles per second. The effect of residual positive ionization from the positive half-cycle is shown to be a minor factor in the radio-noise phenomena of the negative-voltage cycle.

4. The phase of initiation of audible sound and visible light radiations coincides with that of radio noise.

5. Positive direct current on a smooth conductor produces no radio noise with voltages up to double the normal peak threshold voltage.

6. With negative direct current, the most severe radio noise occurs with a perfectly smooth conductor. Weathering and most contaminations reduce the radio noise considerably.

7. Water on the conductor causes severe radio noise with positive direct voltage but eliminates radio noise with negative direct voltage.

8. Radio noise from corona on conductors with negative potential may be controlled by two methods. A smooth coating of high work function will eliminate radio noise by preventing electron emission. A rough, pointed surface of low work function will facilitate electron emission and reduce the severity of the corona current pulses.

9. Radio noise on conductors which are periodically wet may be partially controlled in the positive d-c case by the application of a semiconducting coating which has a damping effect on the corona current surges.

10. A modification of this semiconducting coating appears to be the best compromise for control of radio noise with alternating current.

Discussion

Francois Cahen (Electricite de France, Paris, France): Figure 2 of the paper represents the variation of radio noise versus supply voltage on a smooth and perfectly cleaned conductor. In the case of imperfectly cleaned cables such as cables in operation, the character of these curves differs in three ways from that of Figure 2 of the paper:

1. The level of disturbances is much higher.

2. Disturbances start at a voltage lower than the critical voltage.

3. Disturbances grow rapidly at first, then more and more slowly, to reach saturation point when the critical voltage is exceeded.

Therefore, the curves of Figure 2 of the paper must not be used as a basis for a study of the variations of transmission-line-radio disturbances versus voltage.

On the other hand, is not the shape of curves in Figure 3 of the paper caused by a deformation of the space charge due to the proximity of the plate which plays the part of a second electrode?

According to Slemon, the point of a needle sticking out of the cable would not cause any positive corona effect. We have obtained, at Chevilly, France, the contrary result.

The point of a needle placed on a cable was the center of positive brushes which were a source of power losses and radio disturbances. We even have plotted the curves pointing out the increase in disturbance field due to a needle point sticking out of the cable in Figure 1 of the discussion.

We always have observed positive brushes on all asperities visible to the naked eye, whereas negative brushes also occur on asperities invisible to the naked eye, but these can be removed by rubbing the conductor surface with chamois leather.

Maybe Slemon utilized too high a voltage for his experiments, as the explanation given by him of the nonappearance of brushes (on account of the space charge) applies only to voltages distinctly higher than the critical voltage, whereas brushes also appear when the voltage is lower than the critical voltage.

These observations set apart, the bulk of results described by Slemon tally perfectly with those we obtained at the Chevilly 500-kv experimental station, the latter forming the subject of a communication by Renaudin and Pelissier to the Societe Francaise des Electriciens which is to be published shortly.

Harold L. Rorden (Bonneville Power Administration, Portland, Oreg.): It is apparent that there still is considerable work to be done in our study of corona and radio noise before we can design transmission lines with good economy, and tolerable losses and radio-influence levels. Slemon's contribution to our knowledge of this subject is particularly enlightening with respect to several factors that require further study. He not only has given us a better understanding of the characteristics of corona generation, but he also has shown that it may be possible to reduce some of our radio-influence disturbances by relatively simple expedients. If, for example the optimum spacings mentioned by Slemon for the lowest value of radio influence emanating from a conductor could be determined for various operating voltages, we may have a simple and effective method of improving transmission design. The possible control of radio influence by means of conductor coatings appears to have some extensive possibilities. Should such an expedient become possible, it could be very helpful in mitigating troublesome conditions on existing transmission facilities, as well as to permit better economy in the design of future systems.

It also would be helpful if a method were devised for interpreting radio-influence measurements made by means of coupled circuits (the so-called National Electric Manufacturers' Association (NEMA) method) in terms of the magnitude of radio influence that produces disturbances in residences some distance away from transmission line conductors. The sources of corona are undoubtedly best studied by means of directly-coupled circuits, and Slemon's results amply demonstrate the adequacy of this method. At present it is difficult to specify the requirements for high-voltage transmission equipment, in microvolts measured by the NEMA method, in terms of the microvolts per meter that produce undesirable disturbances in household radios.

We hope that Slemon will continue his good work in the study of the causes and methods of mitigating radio disturbances.

Gordon R. Slemon: Cahen has indicated that radio influence may impose a more serious limitation on transmission-line designs than corona losses. From the viewpoint of economics, corona losses could be allowed to increase. The problem is therefore the prevention of increased radio influence with increase in corona loss. The first method by which this may be accomplished is by the use of phase-to-phase spacings which are smaller than would be indicated by normal practice. The corona loss and the radio-frequency energy are both increased by this reduced spacing. The radio-frequency propagations from the line, however, are reduced.

The second, and as yet undeveloped, method may be a conductor coating which will either prevent unstable ion concentrations or damp any impulses which occur. Rorden has indicated the potentialities of such a method of control. The development of such a coating presents severe mechanical as well as electrical problems. The needle points used in the study were attached to a small diameter conductor. The results obtained were found to correspond with those reported in reference 6 of the paper. It is possible that similar points attached to larger diameter cables may give rise to the radio influence noted at Chevilly, France. The author agrees with Cahen's observation that a more detailed study of corona in the critical-voltage region would be desirable.

Temperature Rise Values for D-C Machines

AN AIEE COMMITTEE REPORT

THIS REPORT gives the results of heat run tests made jointly by the Allis-Chalmers Manufacturing Company, Century Electric Company, General Electric Company, Reliance Electric and Engineering Company, and Westinghouse Electric Corporation on a motor exchange test program at the request of the AIEE rotating machinery committee. Motors tested ranged from 1/2 to 50 horsepower and were standard, open, general purpose, 40 degrees centigrade, 1,750 rpm. Temperature rise was determined for continuous and short time load runs by thermocouples built into the windings, by surface thermocouples, by surface thermometers, and by the resistance method. Each method of measurement is compared with the internal hot-spot measurement.

Based on the results, changes are recommended in the standard limits for temperature rise given in Table I of the American Standards Association (ASA) standard C-50 on Rotating Electrical Machinery.[1] These changes include values for class *B* insulation determined by applying the temperature ratios determined by the tests to the recognized thermometer temperatures for class *B* materials. The values for class *H* insulation establish conservative temperature limits for rise by thermometer, with the rise by resistance obtained by applying the temperature ratios as for class *B*.

It is recommended that Table I of the ASA standard be expanded to cover short-time rated motors, and values are given for this purpose.

In March 1945 the AIEE rotating machinery committee instituted a program for determining actual hot-spot temperatures in d-c machines and for comparing these hot spots with the temperature rise as measured by thermometer, resistance, and surface thermocouple. The test program looked toward placing the resistance method on a practical basis for short-time rated and continuous-rated machines, in order to permit its satisfactory use as an alternative method of test.

Efforts by manufacturers and purchasers to use the resistance method have resulted in difficulties and misunderstanding.

Table I of the ASA standard does not adequately cover the resistance method, particularly for machines having short-time ratings.

Method

Five standard, general purpose, open motors rated 1/2, 5, 10, 25, and 50 horsepower, 230 volts, 1,750 rpm, respectively, were tested. They were shunt wound or stabilized shunt with about 10 per cent regulation. Each motor was tested by its manufacturer and then shipped to one of the other participating companies and retested. Therefore, two tests on each motor are reported, with the exception of the 1/2-horsepower motor which was tested by its manufacturer only.

To determine the hot-spot temperature each motor was built with thermocouples embedded in the armature coils outside the conductor insulation but inside the coil insulation, placed one-third of the length of the slot from each end of the slot. An additional thermocouple was placed in the same manner in each end winding half way between the end of the slot and the end of the winding. Thermocouples were embedded in the coils on the main and commutating poles (at the center of gravity of the section of the coil) at the sides and ends of the coils on the respective center lines.

In most cases thermocouple leads were brought to plug receptacles on both the stationary and rotating parts. At the conclusion of each test run the motor was shut down quickly and thermocouple readings taken at time intervals beginning only a few seconds after removal of load. Curves of temperature were plotted against time and extended back to the instant of removing load. However, since the first reading was obtained so quickly there was virtually no extrapolation of the curves sufficient to cause error. It is particularly important to recognize that in such tests as these the thermocouple reading for the end winding at the commutator end may be rising during the first seconds after shut down, because of the heat flow from the hot commutator. Therefore, if readings are not taken quickly enough to determine this rise, erroneous extrapolation of the temperature-time curve will result.

Only temperature rise values at the instant of removal of load and for the highest of the several thermocouples at that instant are reported as hot-spot temperatures.

Thermometers were applied in all cases as specified by AIEE Test Code for D-C Machines[2] without preheating, except for test A of the 10-horsepower, and test B of the 5-horsepower motor, and the highest reading of the highest of the several thermometers is reported only.

Resistance readings were taken on all windings by Kelvin double bridge, and means were taken to get readings within a few seconds after removal of load and at

---

Paper 49-62, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 16, 1948; made available for printing December 29, 1948.

This report was prepared by the AIEE subcommittee on d-c machines of the rotating machinery committee.

Personnel of the AIEE subcommittee on d-c machines: T. M. Linville, *chairman*, Mrs. B. O. Buckland, W. E. Clancy, F. A. Compton, Jr., Lanier Greer, J. L. Hamilton, C. B. Hathaway, V. P. Hessler, W. R. Hough, P. Lebenbaum, C. Lynn, L. G. Opel, D. Ramadanoff, J. F. Sellers, V. B. Honsinger, L. N. Grier.

Curves B show limits, curve A is average

short time intervals thereafter. The reason for this is the same as already described for the hot-spot readings; that is, to determine the temperature at the instant of load removal without possibility of extrapolating the curves erroneously. Only values for the instant of load removal are reported. The resistance of the armature winding was measured both cold and hot between the same two commutator bars marked for the purpose.

Surface thermocouples were applied adjacent to each thermometer and only the highest reading of the highest of the several thermocouples is reported in each case, the same as for thermometers.

All tests were made under carefully controlled conditions and many special provisions were made to eliminate sources of error.

The conditions for the nine tests made by each company on each motor are set forth in Table II which also gives the test results in degrees centigrade temperature rise. The ambient temperature measured in accordance with the AIEE D-C Test Code[2] was subtracted from each reading before it was tabulated.

Results

The results presented in Table II are used in Table III to show the ratio of the temperature rise measured by the different methods to the hot-spot temperature rise and also to the temperature rise as measured by thermometer. Table III is of special value as it relates the results to the two established, available, bases. These bases are, first, the recognized maximum hot-spot temperatures which insulation of the several classes will stand as given in AIEE standard number 1.[3] The second base is the recognized temperature rise allowed when the thermometer method

Table I. Limiting Observable Temperature Rises

The temperature rises in degrees centigrade in this table apply to the several classes of machines as given at the heads of the respective columns			General Purpose	Totally Enclosed		Short Time Rated						Special Purpose Continuous*		
			Continuous			30-Minute to 2-Hour Ratings, Inclusive			Ratings of 15 Minutes or Less					
			Class of Insulation											
			A	A	B	A	B	H	A	B	H	A	B	H
			Column											
Item	Machine Part	Method of Measurement	1	2	3	4	5	6	7	8	9	10	11	12
1	Armature windings	Thermometer	40	55	75	55	75	100	55	75	100	50	70	90
		Resistance	50	65	85	80	110	140	90	120	160	60	85	110
2	Shunt-field windings	Thermometer	40			55	75	100	55	75	100	50	70	90
		Resistance	60	70	90	70	90	120	70	100	130	70	90	120
3	Single-layer field windings with exposed copper	Thermometer	50	65	85	65	85	110	65	85	110	60	80	100
		Resistance	50	65	85	80	110	140	90	120	160	60	85	110
4	Cores and mechanical parts	Thermometer	40			55	75	100	55	75	100	50	70	90
5	Commutators and collector rings	Thermometer	55	65	85	65	85	110	65	85	110	65	85	110

* Generators having a 2-hour, 25 per cent overload rating will have temperature limits 10 degrees lower than as given in columns 10, 11, and 12 for the continuous load; and the same as given in columns 4, 5, and 6 at the end of the 2-hour overload.

Figure 10. (top)

Figure 11. (center)

Figure 12. (bottom)

Figures 7 to 12. Thermometer, hot spot, and resistance data from Table II for 150 per cent, 30-minute operation

Curves B show limits, curve A is average

is used. These allowances measured by thermometer have given satisfactory life of electric apparatus for many years.

Therefore, there are two factors to keep in mind when setting up a table of limiting values covering all methods. First, it is not desirable to raise the recognized hot-spot limits. Second, it is not desirable to lower any of the thermometer limits which years of practice have proved satisfactory. The results show that the limits in both cases were originally established in a compatible manner so that a table of limiting values covering all methods can be set up based on the present results, without violating established general principles.

To correlate allowable maximum temperature rise by thermometer with the limiting hot-spot temperature rise, Figures 1, 2, and 3 are presented. These figures show for all tests made the rise measured by thermometer plotted against the hot-spot rise measured for each winding. Lines marked *B* show the limits of variation among the motors and the line marked *A* is the average result for all the motors.

From these figures a table of limiting values can be established. The vertical line representing the limiting hot-spot rise should be to the right of the test points but not higher than the established limit for the particular class of insulation. Since the test points are all for motors with class *A* insulation the vertical line in the figures is drawn correspondingly. The horizontal line representing the limiting thermometer rise is drawn to intersect the vertical line at line *A* or in order to be conservative, somewhat below it in some cases. It should also be higher than any of the test points.

To correlate allowable maximum temperature rise by resistance with the limiting hot-spot temperature rise, Figures 4, 5, and 6 are presented. The test points are plotted and the vertical and horizontal lines are drawn in the same manner as for Figures 1, 2, and 3.

Figures 7 to 12 inclusive give comparable data for 30-minute runs at 150 per cent load. These figures are used in the same way as before to determine limiting values for 30-minute rated machines.

Figures 13 to 18 inclusive give the data for 15 minute load runs at 200 per cent load. These figures are used to determine limiting values for 15 minute rated machines.

Discussion of Results

A number of questions arise about the data and results. For example, in the case of the 25- and 10-horsepower motors, Tables II and III show higher temperature rise measured by resistance than by the hot-spot thermocouples embedded in the armature winding. This result is caused by normal variations experienced in using the resistance method on armature windings where the mean temperature of the winding is nearly the same as the hot-spot temperature. This is the case for these two particular motors. Figures 4 to 6, 10 to 12, and 16 to 18 inclusive in each instance, show the variation in results which may be expected using the resistance method. Generally speaking, the lower the winding resistance and the lower the temperature rise, the greater is the variation.

Although the data show higher temperature rise by resistance than the hot-spot temperature rise in some instances for the 10-horsepower and 25-horsepower motors, the hot-spot temperature rise is normal in relation to the temperature rise measured by thermometer in the same instances. This fact indicates that the values for hot-spot temperature rise are reasonably accurate. When the data are used to determine allowable limits by the method shown in Figures 1 to 18 inclusive, the effect of inaccuracy of any particular test point is reduced.

Another point in question is the increase in the allowable hot-spot temperature from 55 to 65 degrees shown in Figures 3 and 6, and in Table I of this report. The figures show that there is no choice unless the time-honored allowance of 40 degrees centigrade rise by thermometer is to be lowered. It appears reasonable in the case of stationary field coils not to change the thermometer standard and to recognize the corresponding hot-spot temperature rise as 65 degrees centigrade.

A third question arises in regard to Figures 7 to 12 inclusive, where the hot-spot temperature rise is recognized as 80 degrees centigrade. This is done to hold onto the standard of 55 degrees centigrade as the temperature rise allowed by thermometer for short time rated apparatus consistent with AIEE standard number 1A[4] and Table I of ASA-C50.[1] The test data show that 80 degrees centigrade is the corresponding hot-spot temperature rise. This higher value is justified for the reasons given in AIEE standard number 1A, paragraph *1A-9*, explaining that the additional temperature rise is allowed to secure approximately the same life for short time rated machines as for continuous rated ones.

For the same reasons the hot-spot temperature rise for machines rated 15 minutes or less is recognized as 100 degrees centigrade, shown in Figures 13 to 18 inclusive, except for shunt field coils, Figures 15 and 18, where the hot-spot temperature rise is recognized as 80 degrees centigrade, corresponding to 55 degrees centigrade rise by thermometer and 70 degrees centigrade by resistance.

It should be recognized that on very brief load runs the surface of the shunt field winding is generally heated by radiation from the commutating field winding, causing the surface temperatures to be as hot as the mean temperature of the winding. It is not recommended that for class *A* insulated, short time rated

machines a temperature rise by thermometer or resistance be allowed which is higher than that corresponding to 80 degrees centigrade rise at the hot spot.

Figures similar to 1 to 18 may be plotted for the 1-hour and 2-hour test runs. The results for these correspond closely to Figures 1 to 6 inclusive, for continuous load tests. That is, lines *A* and *B* of Figures 1 to 6 represent the 1-hour and 2-hour tests although the vertical and horizontal lines representing the maximum allowable temperatures should be changed to allow for the short time rating rather than continuous rating.

Basic test conditions are given in Table IV to help answer anticipated questions about variations between the test results.

Conclusion

The conclusions which have been drawn from the test results reported are given in Table I of this report. This table is formed by tabulating the values for the horizontal temperature rise lines on Figures 1 to 18 inclusive, as basic data for class *A* insulation for open and short time ratings. This results in no change in the temperature rise values by thermometer from those given in the present Table I of ASA-C50.[1] New values for rise by resistance are obtained.

The values for class *B* insulation measured by thermometer are retained as in the present Table I of ASA-C50. New values for class *H* insulation measured by thermometer are added determined in accordance with the principles of AIEE standard number 1.[3] Values measured by resistance are then determined for class *B* and class *H* insulations to give the same ratio between rise by resistance and rise by thermometer as was found from the tests for class *A* insulation.

Therefore, from the test results this table has been compiled and the committee recommends that it replace Table I of ASA-C50 (after due discussion and verification). It is believed that this table adequately covers the resistance method as an alternative test procedure for short-time rated machines as well as continuous rated machines.

The test results verify the interchangeable use of thermometers and surface thermocouples so that no special values are necessary for the latter. A free choice of either instrument is indicated except for motors below one horsepower.

Discussion

B. H. Caldwell and **G. H. Gunnoe** (General Electric Company, Schenectady, N. Y.): Test results of temperature rise as measured by: embedded thermocouple; resistance; surface thermocouple; and surface thermometer are given for motors rated 1/2, 5, 10, 25, and 50 horsepower in the report. Based on the results of these tests, Table I is presented, which includes limits of temperature rise as measured by thermometer and by resistance. It is finally recommended by the committee that Table I of the report replace Table I of ASA-C50 (See Table I of this discussion).

Serious consideration of this proposal raises two questions. First, do test results indicate the resistance measurement to be a better method than the surface thermometer? In the discussion presented by M. A. Baker, a table is given (Table III of the discussion) which demonstrates that more consistent results were obtained in this series of tests by thermometer than by resistance. This result favors the use of the surface thermometer. However, the resistance method does, on the average, approach the hot-spot temperature more closely than does the surface thermometer. This is particularly true in the case of short time overloads. In this respect the resistance method is to be preferred.

The second question which arises is: are the results typical for all sizes of d-c machines? Since Table I of ASA-C50 applies for essentially the complete range in sizes and ratings of d-c machines, this question is of utmost importance. Data for medium size machines has been given to the committee and is summarized in M. A. Baker's discussion. Data for armored motors was given in a paper by F. A. Compton, Jr. in 1943.[1] Based on this paper and similar data on large d-c motors and generators, a Proposed New Table for "Limiting Observable Temperature Rise," was presented to the committee by T. M. Linville in 1945. A copy of this table is included with this discussion (Table II of the discussion). All of these data are in radical disagreement with the proposed revision of Table I, ASA-C50, now proposed by the committee (See Table I of the report).

Figure 1 of the discussion shows additional data which have been accumulated from tests taken on large d-c machines. Results are shown for machines with class *A*, *B*, and *H* insulation. All machines were larger than 1 horsepower per rpm. These data have been screened to eliminate questionable results, and it is felt that the points indicated represent best application of test procedure. All data represent continuous heat runs; none are for short time runs. The straight line shown in Figure 1 of the discussion, approximates the median line, and it is interesting to note the close agreement with the Proposed New Table. While it is clear both from these data, and from the data presented in the committee report, that there is no fixed ratio relating rise by resistance and rise by thermometer, it is evident that the average ratio for large machines differs greatly from that proposed in Table I of the report.

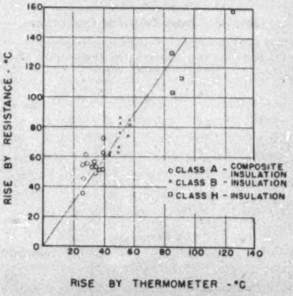

Figure 1. Comparison of armature temperature rise by resistance and by thermometer for large d-c machines

It is thus apparent that the proposed revision of Table I, ASA-C50, is not consistent with the present standards for large d-c machines. This proposal is equivalent to revising the present standards to limit rise by thermometer to 30 degrees centigrade for large, class *A* machines. The present practice has been in force for many years, and its successful operation needs no defense. Therefore, it would seem mandatory that the proposed revision be modified to permit limits of rise by resistance for large machines as indicated in the Proposed New Table (Table II of the discussion).

Even though the resistance method appears to be less accurate than the surface thermometer, the fact that it more nearly approaches the hot-spot temperature lends encouragement to its use. Of the various methods used, the embedded thermocouple has the dual advantage of accuracy and of allowing measurement of a temperature which closely approaches the hot spot value. Use of this technique, or a modification thereof, might prove feasible for large machines; just as in the case of large a-c machines the use of an embedded temperature detector is recognized and used.

Any discussion of allowable temperature rise must recognize the type or class of insulation. The true limit is of course set by that value of temperature which permits satisfactory life. Thus, it is common practice to use a composite insulation for armature coils for large d-c machines; the insulation around the conductor and the main portion of the coil insulation being composed of mica. Even though rated as class *A*, for such an insulation the hot-spot temperature rise can safely approach the class *B* value, provided the temperature of the class *A* material which forms the external covering of the coil does not exceed its safe value. In this way composite insulation has been available for use in compensating for the little recognized yet wide discrepancy between temperature rise as measured by surface thermometer and the actual hot-spot value.

The present accelerated use of new synthetic materials offers the prospect of insulating materials with temperature endurance limits in between class *A* and *B* materials, as well as extending the limit recognized heretofore for class *B* materials. These developments promise new latitude for the design engineer, and it is to be hoped that revision of the standards can be accomplished so that efficient use of these new materials will be promoted rather than discouraged.

REFERENCE

1. TEMPERATURE LIMITS AND MEASUREMENTS FOR RATING OF D-C MACHINES, F. A. Compton, Jr. ELECTRICAL ENGINEERING (AIEE TRANSACTIONS), volume 62, December 1943, pages 780–85.

John L. Fuller (Reliance Electric and Engineering Company, Cleveland, Ohio): The report presents data on a well-conceived series of tests designed to establish suitable limits of temperature rise by resistance method. The results raise many questions, some of which were answered in the report.

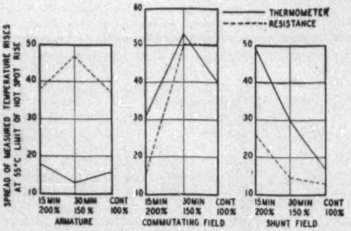

Figure 2. Spread of measured temperature rises versus hot spot

A most glaring result is the evidence of inability, even with the most carefully controlled laboratory techniques, to achieve anything approaching consistency in relationship of hot spot to temperature measurement by resistance or thermometer. This is particularly true for armature rise by resistance, which shows great variations.

As an aid to evaluating the spread of results, Figure 2 of the discussion shows the spread of measured temperature rise at the 55 degrees centigrade limit of hot-spot rise for each of the conditions represented in Figures 1 through 18 in the report. Data for Figure 2 of the discussion were secured from the points at which the upper and lower lines on Figures 1 through 18 cross the vertical 55 degree centigrade line.

From study of Figure 2 of the discussion, the following conclusions may be reached:

1. It is highly questionable, in view of the wide discrepancies in test results (about $2^1/_2$ times as much as by thermometer) whether or not a standard should be established for armature rise by resistance.

2. Shunt field rise can be measured more accurately by resistance method than by thermometer, and a standard should be established.

3. Commutating field rise can be measured about as well by resistance as by thermometer, and a standard for this is probably in order.

F. R. Terrant (Reliance Electric and Engineering Company, Cleveland, Ohio): Table I of the subcommittee's report proposes for motors rated 30 minutes to two hours a limiting observable temperature rise of 55 degrees centigrade by thermometer and 80 degrees centigrade by the resistance method for class *A* insulation. A study of tests on 26 30-minute and 60-minute duty motors, selected at random from our regular production test files, shows that the temperature rises by resistance range from 48 per cent above to 60 per cent below the rises by thermometer. Test department tests, although not as accurately made as the laboratory tests given in the report, do indicate that the majority of short-time rated motors meeting a 55 degree centigrade rise by thermometer would also meet the 80 degree centigrade rise by resistance which is 45 per cent above the 55 degrees centigrade by thermometer.

The temperature rise limits proposed for generators having a 2-hour 25 per cent overload rating as described in the footnote of Table I of the report would limit class *B* machines to 60 degrees centigrade by thermometer for the continuous rating. It would seem that the temperature rise is unduly limited in this instance and full advantage of class *B* materials would not be realized.

It is suggested that consideration be given to using column 11 directly for the continuous rating, and column 5 for the overload rating.

P. L. Alger (General Electric Company, Schenectady, N. Y.): This report gives important and interesting data relating the internal temperatures of small d-c machines to the measured values. Table I of the report summarizes the information in a very clear way, providing a basis for the intelligent development of better d-c machine standards.

There are three points I wish to emphasize in regard to Table I.

The purpose of the table is to limit the hot-spot temperatures to permitted values for each type of machine and service. The present method of setting temperature limits measured by thermometer is now shown to be a very crude way of accomplishing this, as the hot-spot temperature varies widely for a given thermometer rise, depending on the type of machine, and the duration of the test.

It is clear that the resistance rise method is preferable, as it gives a much closer approximation to the hot-spot temperature; but here also there are wide variations. The proposed new table (see Table I of the report) gives resistance rise values fairly equivalent to the thermometer values for the small or moderate sized open machines included in the test program given in the report, but the values do not apply to large or highly ventilated machines.

For, large machines with naturally high velocities of cooling air, and also highly ventilated small machines, will have considerable greater values of rise by resistance for the same thermometer rise than shown in Table I, due to the greater rate of heat flow through the insulation. I believe, for example, that many large continuous rated machines with less than 70 degrees centigrade rise by thermometer have actual values of armature rise by resistance of 100 degrees centigrade, or even more, as compared with the 85 degrees centigrade value given in column 11 of the table. Likewise, moderate sized machines, with short-time ratings of 15 minutes or less, which meet 75 degrees centigrade rise by thermometer, may have armature winding temperatures by resistance of the order of 150 degrees centigrade, as compared with the 120 degrees centigrade value given in column 8 of the table.

I believe that the resistance method should be recognized in the standards as an optional, but not a mandatory, way of measuring temperature, at least for moderate sized, and enclosed, d-c machines. The test data show wide variations in the temperature values found by different methods and different observers, the variations in the resistance values being generally somewhat greater than those between thermometer values. The resistance method is increasingly difficult to use, the lower the ohmic resistance to be measured, so that its regular use on large armatures may be a long time in coming. Nevertheless, I believe that the resistance method will be as reliable in most cases and more reliable in many than the thermometer method, besides giving temperatures much closer to the hottest-spot values. A statistical analysis of the ratios of resistance to thermometer and to hot-spot rises given in the report indicates that the errors in the resistance method are due largely to a displacement of all the values from the expected level, rather than errors in individual readings. This suggests that great improvements can be made with adequate experience and equipment.

In undertaking to define the desired hot-spot limits by resistance rise values, we should give the designers freedom to continue practices known to be satisfactory with existing thermometer limits. This in turn will permit higher hot-spot temperatures than the conventional limits of 105 and 130 degrees centigrade for class *A* and *B* materials; and it also will allow higher operating temperatures in some types of machines, for which the thermometer rise values have been unduly limiting in the past.

In undertaking this necessarily long range program of establishing new resistance rise temperature limits, three points need to be kept in mind:

1. In choosing the new resistance rise values, consideration should be given to the factors of overload capacity, temperature creep, stalled time limits, thermal expansion, and commutation and bearing limits, as well as the temperature life of the insulation itself, in the expected service. AIEE Standard Number 1[1] fully recognizes this need for choosing temperature limits on a broad economic basis, and encourages the adoption of different limiting values for different types of apparatus or service.

2. Existing AIEE standards for control equipment have for many years allowed 85 degrees centigrade rise by resistance with a 40 degree ambient, or 125 degrees centigrade hot-spot temperature, for class *A* coils in continuous operation. Also, the AIEE railway standards have for many years recognized 120 degrees centigrade rise by resistance for armatures, and 130 degrees centigrade rise by resistance for fields over a nominal 25 degrees centigrade ambient, or 145 to 155 degrees centigrade hot-spot temperature, for class *B* insulation. Thus, existing standards now recognize a spread of 20 to 30 degrees in hot-spot limits for the same insulation class, depending on the type of apparatus concerned.

3. I believe that the duty factor method of rating d-c machines for short-time or intermittent service should ultimately replace the present short-time rating methods in the standards. For, both the wide range of permissible values of hot-spot temperature for short-time rated machines, and the inaccuracies in measuring the rapidly changing temperature in such cases, make it impractical to set any new limiting values for them. On the other hand, the duty factor method of rating, in which the machine is run for definite time periods with intervals of rest between, allows the machine to reach a limiting temperature that is measured readily, and should be roughly the same for a wide variety of ratings. This method is now well recognized in the standards of the Iron and Steel Engineers, and, therefore, has the backing of long experience.

Summing up, I hope that the AIEE machinery committee and the standards committee will carry the development of new d-c machine standards forward with vigor, looking to improved techniques in the resistance method of measurement; to the recognition of the resistance method as the basic standard; the adoption of higher temperature limits by resistance, chosen on an economic basis; and the adoption of the duty factor method of rating in place of the short-time method.

1. See reference 3 of the report.

M. A. Baker (General Electric Company, Fort Wayne, Ind.): The motors tested in this AIEE test program are small machines and it is reasonable to expect different data on larger units which run at higher peripheral speeds and are often better ventilated. In fact, this is the actual case and a table of limiting temperature rise values covering d-c machines broadly must take into account experience with large machines and test results obtained on them.

The proposed new table (see Table I of the report) based on the data obtained from this test program proposes 50 degree centigrade rise by resistance and 40 degree centigrade rise by thermometer for armatures of class *A* continuous rated general purpose machines. For special purpose class *A* continuous rated machines, the proposed rise by resistance limit for armatures is 60 degrees centigrade. The ratio of rise by resistance to rise by thermometer is 1.25 for the armatures of general purpose class *A* machines, and 1.2 for class *A* special purpose machines. Five years ago, the General Electric Company submitted to this committee a summary of a number of heat runs taken on larger machines. These data indicated a rise by resistance to rise by thermometer ratio of 1.4 for continuous rated class *A* machines, and 1.6 for continuous rated class *B* machines. At that time, ratios of 1.4 and 1.43 were recommended for class *A* and *B* machines respectively. It appears that the new proposed table limits the rise by resistance on armatures to too low a value based on operating experience, and data obtained on larger units over a long period of time.

Table III of the discussion shows the per cent variation in the heat run results of the two independent tests made on the four motors. The per cent variation is calculated by taking the difference in temperature rise between heat runs *A* and *B*, and dividing the difference by the average temperature rise.

One of the conclusions that can be drawn from the data in Table III of the discussion, is that the temperature rise on low resistance circuits (armature and commutating fields) can be measured more consistently, by independent testers, by the thermometer method than it can by the resistance method. This is true in spite of the extraordinary care and laboratory equipment used in making these tests. If ordinary commercial test technique had been used, the resistance data would undoubtedly have shown still more variation.

Rise by resistance is a specialized tool by which we can get additional knowledge of our machines. However, standard commercial test practice should be limited to the thermometer method because of the special equipment and technique required and because of the relatively greater care that must be exercised to get equally reliable results. The test data show that the ratio of thermometer temperatures to internal hot-spot temperatures is as definite as is the ratio of resistance temperatures to hot-spot temperatures. Therefore, with proper allowances set up, the thermometer method is a reliable measure of internal hot-spot temperatures.

Since the resistance of the shunt field circuit is much higher than that of the armature and commutating field, the problem of contact resistance is not present. The resistance of shunt fields can be measured more accurately than that of the armature and commutating fields, so that rise by resistance is a reliable test for shunt fields. The foregoing data indicate that rise by resistance can be checked more consistently on shunt fields than can rise by thermometer. Based on many years of experience, the proposed increase in shunt field temperatures is entirely reasonable in the light of modern insulation. The increased rise by resistance limits proposed in the new table I for shunt fields is heartily indorsed.

Table IV. Ratio of Temperature Rise by Hot Spot to Temperature Rise by Resistance

Taken from Tests on Five Motors, Average Values

Armature	
Full load continuously	=0.985
25 per cent overload for 2 hours	=0.972
50 per cent overload for 1 hour	=1.031
100 per cent overload for 15 minutes	=1.005
Commutating Pole Coils	
Full load continuously	=1.038
25 per cent overload for 2 hours	=1.001
50 per cent overload for 1 hour	=1.039
100 per cent overload for 15 minutes	=1.065
Shunt Windings	
Full load continuously	=1.118
25 per cent overload for 2 hours	=1.093
50 per cent overload for 1 hour	=1.14
100 per cent overload for 15 minutes	=1.12

H. E. Stokes (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The tests on which this report are based, were made on small industrial motors ranging from 1/2 to 50 horsepower at 1,750 rpm on standard open-type general-purpose motors. Table Number I of ASA C-50 1943 (See Table I of discussion), governs existing temperature rises for all classes of d-c rotating machines larger than 560 watts, and supersedes AIEE tables formerly applicable. Based on the tests made on these five relatively small motors, the report establishes ratios of rise by resistance/rise by hot spot; rise by resistance/rise by thermometer and so forth. Table III of the report tabulates all of these ratios which are obtained from the temperature rises given in Table II of the report. I have changed the form of these ratios to those shown in Table IV of the discussion, averaging the test results obtained on the five motors. The temperature rises obtained by thermometer and those obtained

Table V. Ratio of Hot-Spot Temperature Rise to Thermometer Temperature Rise

Tests Taken on Five Motors—50, 25, 10, 5 and 1/2 Horsepower Ratios Given are Average of the Five Motors

Armature	
Full load continuously	=1.23
25 per cent overload for 2 hours	=1.23
50 per cent overload for 1 hour	=1.42
100 per cent overload for 15 minutes	=1.7
Commutating Pole Coils	
Full load continuously	=1.16
25 per cent overload for 2 hours	=1.2
50 per cent overload for 1 hour	=1.07
100 per cent overload for 15 minutes	=1.396
Shunt Coils	
Full load continuously	=1.81
25 per cent overload for 2 hours	=1.72
50 per cent overload for 1 hour	=1.56
100 per cent overload for 15 minutes	=1.27

by surface thermocouple on the average may be taken as interchangeable and surface thermocouples are hereafter referred to as thermometer readings.

An inspection of Table IV of the discussion, which shows the ratio of hot-spot rise to/temperature rise by resistance for the armature, shows a ratio of 1.0 ± 3 per cent. For the commutating pole coils the ratio of hot-spot rise to/temperature rise by resistance is 1.0 plus a maximum of $6^{1}/_{4}$ per cent minus nothing. The shunt field coils show the only significant departure, where this ratio varies from 1.093 to 1.14.

Table V of the discussion shows corresponding values of 1.0 plus 23 per cent, plus 70 per cent for the armature, 1.0 plus 7 per cent, plus 40 per cent for the commutating pole coils and 1.0 plus 27 per cent, plus 81 per cent for the shunt fields.

In a similar manner Table VI of the discussion shows for these values armature, 1.0 plus 27 per cent, plus 76 per cent, commutating pole coils 1.0 plus 12 per cent, plus 36 per cent and shunt coils 1.0 plus 18 per cent, plus 64 per cent.

Tables IV, V, and VI of the discussion show the highest ratio of the fraction of hot-spot temperature rise to/thermometer-temperature rise, or the fraction, resistance-temperature rise to/thermometer-temperature rise to be 1.81. It should be remembered, however, that these ratios are obtained on small size industrial machines. If taken on large machines, the ratio fraction of hot spot rise to/rise by thermometer may be much greater, perhaps 50 per cent or more. The writer of these comments, therefore, feels that the values obtained on these small size machines cannot be used safely to amend temperature rise of Table I of ASA, C-50, 1943, which covers all sizes of machines above 560 watts.

Table VI. Ratio of Temperature Rise by Resistance to Temperature Rise by Thermometer

Tests Taken on Five Motors, Average Values

25 per cent overload for 2 hours	= 1.56
50 per cent overload for 1 hour	= 1.4
100 per cent overload for 15 minutes	= 1.18

Past and present AIEE and ASA rules have probably shown a hot-spot temperature higher than the measured temperature rises by thermometer. This report shows that the difference between measured temperature rises and hot-spot temperature rises is appreciably higher than the values that have been used in the past. The writer would like to point out that over a period of decades, machines which have met the measured temperature rises have been operating with hot-spot temperatures actually higher than the values which have been set up in the past by standards for measured temperature rises with satisfactory operation from the standpoint of insulation, life, and general performance. Therefore, if the rules are changed to permit higher hot-spot temperatures, we would simply be recognizing conditions under which machines have been operating in the past, which conditions have actually been at higher temperatures than were considered in the past.

In this same connection most industrial-type machines have general ratios between armature diameters and core lengths. Large size power d-c machines, particularly motors, may have very large differences in the ratio of armature diameters to core length. Some machines have an armature diameter in the neighborhood of 4 feet and may have core lengths as short as 8 inches and as long as 48 inches. Obviously the hot-spot temperature distributions in the armature copper portion that is embedded in the slots, would be entirely different in a machine whose core length is six times as long as another machine. The end winding extensions in these machines of two extreme core lengths could be identical.

The new suggested Table I in the report should be restricted to small industrial-type machines only. Before the same kind of table is made available for large size industrial d-c machines, a considerable amount of tests and investigation will have to be carried out on the range of sizes of machines encountered for machines of this type, to determine what the actual hot-spot temperatures encountered are. Such tests are not as easy to make as in the case of the small industrial machines, since these large machines cannot be made for test and shipped to the various manufacturers for interchanging test procedures. They must be made on production machines going through for customers, and such procedure will take a long time, not only to obtain tests, but to correlate data and secure the same type of information.

F. M. Scott (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): The entire test program concerned the testing of motors up to and including 50 horsepower. The results obtained and the conclusions outlined in the report appear significant and logical. However, the application of these conclusions to large machines is not feasible.

Large machines, because of special requirements and varying speeds required, have drastically different ratios of diameter to length and large ranges of peripheral speeds. The few tests we have made on such machines, where temperature rise was determined by resistance rise, indicate that ratios of rise by resistance to rise by thermometer are considerably higher than those given in Table I of the report for all windings.

It has not been our practice to check temperature rise by resistance and consequently have very little test data we could furnish. We had in mind presenting the test results on the few machines we have checked, but such tests have varied so widely, with some ratios as low as 1.0 and some as high a 2.0, that we decided that it will be necessary to check a larger number of machines before submitting test data that we would consider reliable. Undoubtedly the tests made by General Electric and Westinghouse are significant as they have been made on a large number of machines.

Measuring temperature rise by resistance introduces new problems that must be overcome by the establishment of reliable commercial test procedure for such measurements. The percentage error due to contact resistance is definitely much greater on armature and interpole windings of large machines, and particularly so when compared with shunt field windings. As results vary so widely on small and large machines additional consideration will have to be given whether one table can be used later on all machines, or whether two or more tables will be necessary. It is possible that present division of motors below and above 200 horsepower could be used for such tables.

We recommend the acceptance of the proposed new table as part of ASA-C50 standards stipulating that this table is applicable for machines up to and including 50 horsepower, and the present table now listed in ASA-C50 apply to machines above 50 horsepower. We further recommend that the test program be continued on large machines so that results can be consolidated and averaged for a dependable comprehensive standard of temperature rise.

George Grant (Dow Corning Corporation, Midland, Mich.): This report is a significant study of the relation between hottest spot temperature rise and temperature rise as measured by thermometer, resistance, and surface thermocouples. There appears to be one error of fact, however, in the figures and in the discussion of them. Furthermore, no values are given for class *H* totally-enclosed motors rated for continuous operation and the values given in column 12 of Table I of the report are much more conservative than those given in columns 10 and 11. In view of the published and unpublished reports on the accelerated life testing of class *H* and other classes of insulation under carefully controlled conditions, exception is taken to this omission and to the ultra-conservative limits placed on this class of insulation.

In Figures 1 through 18 a vertical line is drawn at 55 degrees centigrade to represent the hot-spot temperature rise as given in AIEE Number 1,[1] wherein the hot-spot temperature rise for class *A* is set at 65 degrees centigrade.

Considering a vertical line representing AIEE Number 1, drawn at 65 degrees instead of 55 degrees centigrade in Figures 1, 2, 4, and 5 of the report it would appear that slightly higher values for temperature rise by resistance and by thermometer might be recommended for armatures and commutating fields. In Figures 3 and 6 a line drawn at 65 degrees centigrade coincides with the values proposed for shunt fields in this report and eliminates the need for paragraph 3 under Discussion of Results.

Relocation of the line representing AIEE Number 1 in the other figures reduces the proposed increase in hot-spot temperature from 25 to 15 degrees centigrade for all parts of motors with a short time rating of 30 minutes to two hours and for the shunt fields of motors having a rating of less than 15 minutes. Similarly proposed increases in hot-spot temperature for armatures and commutating fields rated for less than 15 minutes are reduced from 45 to 35 degrees

Table VII

		140°C. Hot-Spot Temperature Rise Class A Ratio	140°C. Hot-Spot Temperature Rise Class B Ratio	190°C. Hot-Spot Temperature Rise Class A Ratio	190°C. Hot-Spot Temperature Rise Class B Ratio
Armature windings	Thermometer	116	119	158	161
	Resistance	131	140	178	190
Shunt field windings	Resistance	140	152	190	205
Single layer field windings with exposed copper	Thermometer	131	140	178	190
	Resistance	131	140	178	190

centigrade. To maintain the increases in hot-spot temperatures proposed in this report, new hot-spot temperature rises of 90 and 110 degrees centigrade should be allowed, permitting somewhat higher thermometer and resistance values.

It is difficult to account for the omission of values for class *H* insulated, totally-enclosed motors rated for continuous operation. It is true that there has been some difficulty with commutation and brush wear in totally enclosed, class *H* insulated d-c motors, but a table of limiting temperature rises does not appear to be the proper place to resolve problems not related to the heat-stability of the insulating materials. The commutation problem may be solved before the proposed standards are adopted. In any case the solution will come more rapidly if limiting observable temperature rises for class *H* insulated motors of this rating are included in Table I of the report.

AIEE Standards Number 1 gives tentative approval to a hot-spot temperature rise of 140 degrees Fahrenheit for class *H*. This is a very conservative value as indicated by tests recently concluded and reported in a paper which will be submitted for presentation before the 1949 Midwest meeting of the AIEE. Test results reported in this report indicate that the life of class *H* and class *B* motors will be equal when the class *H* machine operates at a hot-spot temperature 100 degrees centigrade above that of the class *B*. This would indicate a hot-spot temperature rise of 190 degrees centigrade for class *H*.

Using these values, limiting observable temperature rises can be calculated for totally enclosed class *H* motors rated for continuous operation. This has been done by first determining the ratio of the values given in columns 2 and 3 to the hot-spot temperature rise values for class *A* (65 degrees centigrade) and class *B* (90 degrees centigrade) respectively. This ratio was then multiplied by the hot-spot temperature rise as set by AIEE Number 1 (140 degrees centigrade) as well as by that indicated by the tests recently concluded (190 degrees centigrade). These values are given in Table VII of the discussion.

It is suggested that consideration be given to the addition of a column to Table I giving values at least as great as those shown in Table VII of this discussion, for a hot-spot temperature rise of 140 degrees centigrade for class *H* totally-enclosed motors rated for continuous operation.

It is proposed in the report that the hot-spot temperature rises specified in the AIEE Standard Number 1[1] be increased by 15 and 35 degrees centigrade for short-time ratings, as shown in Figures 7 through 16 of the report. It would seem reasonable and consistent, therefore, to allow an equal increase for short time rated class *H* motors. The hot-spot values for class *H* would then be 155 and 175 degrees centigrade for these ratings. If a less conservative rating of 190 degrees centigrade hot-spot temperature rise were accepted for class H, continuous duty, the proposed temperature rises would become 205 and 225 degrees centigrade. Using these four values, the limiting observable temperature rises given in Table I, columns 6 and 9, have been recalculated. This has been done by first determining the ratios of the values given in columns 4 and 7 to the corresponding hot-spot values taken from Figures 7 through 16. These ratios were then multiplied by the hot-spot temperature rises proposed for short-time ratings. The results are given in Table VIII of the discussion.

It will be noted that the values, based on a continuous rating of 140 degrees centigrade hottest spot temperature rise, range from 4 degrees below to 16 degrees above the corresponding values given in columns 6 and 9 of Table I. The values given in column 6 of Table I average about 10 degrees centigrade below those shown in Table VIII of the discussion. The values given in column 9 of Table I are about the same as those shown in Table VIII.

The addition of 10 degrees centigrade to each of the hot-spot temperature rises used to calculate the values given in columns 6 and 9 of Table I would seem to be a minimum correction. Because the rating of 140 degrees centigrade hot-spot temperature rise for class *H*, AIEE Number 1, is ultra-conservative these hot-spot temperature rises might be increased by as much as an additional 50 degrees centigrade.

Table VIII

		Column 6 at 140°C. Continuous	Column 6 at 190°C. Continuous	Column 9 at 140°C. Continuous	Column 9 at 190°C. Continuous
Armature windings	Thermometer	107	141	96	124
	Resistance	155	205	158	202
Shunt field windings	Thermometer	107	141	107	141
	Resistance	136	179	136	179
Single layer field windings with exposed copper	Thermometer	126	167	114	146
	Resistance	155	205	158	202

The values given in Table I, column 12, for special purpose continuous duty motors are excessively conservative. They range from 30 to 40 degrees centigrade below the values based on AIEE Number 1 standards and suggested in this discussion for totally-enclosed, continuous duty class *H* motors. They are 70 to 80 degrees centigrade below the values based on a hot-spot temperature rise of 190 degrees centigrade for totally-enclosed continuous duty class *H* motors. It certainly seems conservative to suggest that the values given in column 12 of Table I be increased by at least 35 degrees centigrade.

Appropriate temperatures for cores and mechanical parts or for commutators and collector rings in class *H* motors are not suggested in this discussion because the data necessary for such calculations are not given in the report.

It has been suggested that limiting observable temperature rises for totally-enclosed class *H* motors rated for continuous duty be included in Table I. It has been suggested that the values given in columns 6 and 9 of Table I be increased by adding at least 10 degrees centigrade to the hot-spot temperature rises used in calculating these values. It has also been proposed that the values given in column 12 of Table I be increased by at least 35 degrees centigrade. These increases are consonant with the very conservative standards set for class *H* insulations in AIEE Number 1. All of these proposed increases are far below those which would be justified if the AIEE standard were revised to recognize hot-spot temperature rise of 190 degrees centigrade, for class *H*. These suggestions are intended to give design engineers an opportunity to exploit to the fullest extent the exceptional heat stability of class *H* insulations.

REFERENCE

1. See reference 3 of the report.

C. B. Hathaway (Westinghouse Electric Corporation, Buffalo, N. Y.): The report seemed to indicate that the present addition of 1 per cent of the output for the stray load losses is low. It is indicated that the actual stray load losses would be near 2 per cent. It must be recognized that these measurements were made on machines of 50 horsepower and smaller and the results, of course, are limited to this range. There is no evidence available as to what the losses may be in larger machines.

Furthermore, the values themselves are open to question. The method employed was by measuring the output with the dynamometer. A small quantity obtained by subtracting one large one from another large one is inherently subject to great error.

Therefore, it is my opinion that until a more accurate method can be developed to determine stray load losses that the present 1 per cent allowance should be allowed to stand.

T. M. Linville and Mrs. B. O. Buckland: Grant raises a question about the vertical line drawn at 55 degrees centigrade to represent the hot-spot temperature rise as given in AIEE Number 1.[1] It is true that AIEE Number 1 sets the hot-spot temperature rise for class *A* at 65 degrees centigrade. This corresponds to a hot-spot temperature of 105 degrees centigrade with an ambient temperature of 40 degrees centigrade. The corresponding rise by thermometer is 50 degrees centigrade. However, general purpose, class *A*, open motors are allowed only 40 degrees centigrade rise by thermometer based on a 40 degrees centigrade ambient. The corresponding hot-spot temperature rises are 95 degrees centigrade and 55 degrees centigrade respectively, in accordance with AIEE Number 1.

The method of the report is to establish the ratio of temperature rise by resistance to temperature rise by thermometer as given by the tests. Then this ratio is applied to the standard temperature rise by thermometer for class *A* and *B* insulations and for the several classes and ratings of machines in order to set up the new Table I for ASA-C50 so that it will properly cover the resistance method without any change in the present thermometer values.

This method should also be followed for class *H* insulation but in this case no thermometer values have been set as yet. Hence, the values given in the report for class *H* are highly preliminary and incomplete. All suggestions as to what these values should be is especially appreciated.

The report establishes and clearly shows in Figures 1 to 18 the values of hot-spot temperature rise which correspond to the standard thermometer values as shown by the tests. These are the hot-spot values which should be allowed if the thermometer values are left unchanged as is recommended. These hot-spot values are consistent with the principles set forth in AIEE Number 1A.[2]

Stokes has made an interesting presentation of the test data. He points out that the new Table I given in the report cannot be applied to large machines. He also points out that a long time will be required to get data on large machines and asks why, in view of the limitations of the paper, a definite recommendation is made to revise Table I of ASA-C50 (See Table I of the discussion) on an unrestricted basis.

In regard to the latter question, in the first place the test results show that expansion of Table I is definitely needed if the resistance method is to be a useful method of test. Furthermore, the conclusion seems reasonably justified that expansion of the table based on the tests covered by the report taken on small machines will not worsen the situation with respect to large machines.

As things stand now, it may be inferred from the standards (as is a fact in Navy specifications) that only 10 degrees centigrade additional rise is to be allowed for the resistance method over the thermometer method for all windings. For the purpose of keeping the standards up-to-date, an expansion of Table I is recommended now in view of the time necessary to obtain test data on large machines, remembering that the test program covered by the report was initiated in 1944.

Baker's comments represent a common desire to keep things simple. His tabulation of the data shows a larger variation in results with the resistance method than with the thermometer method. However, the purpose of all temperature tests is to measure the temperature of the hottest spot and because the resistance method comes closer to doing this than does the thermometer method for machines of normal proportions its accuracy is superior in spite of greater percentage variation in results. Moreover, the resistance method is the preferred standard method for railway motors and generators and its use by engineers to learn the maximum about machines of all types is commonly known. Therefore, there is need for standards covering its use so that where appropriate it can be used in commercial transactions without making special design of machines necessary.

Alger, who has been close to the test program given in the report and has contributed much to it, answers in his comments several of the questions raised by other discussors and outlines the program which the d-c subcommittee should carry forward vigorously in the interest of better standards and better machines as a result thereof.

Caldwell's and Gunnoe's discussion relates mainly to big machines and is important and encouraging for many reasons. It indicates that data very likely are already at hand among the manufacturers of big machines and possibly can be collected promptly by the d-c machine subcommittee (an exchange test program would obviously be impractical with big machines). It gives test results on a substantial number of big machines which support the "Proposed New Table" of 1945 which was derived from test results on 19 machines supported by theoretical data presented in 1945. Their discussion also presents data on class *A*, class *B*, and on 4 class *H* machines showing that there is a common average ratio between rise by resistance and rise by thermometer for all these classes as was assumed in the report. They present an alternative proposed new table (See Table II of the discussion) for consideration derived from tests on large machines by the same method as was used to derive Table I of the report from tests on small machines. In response to this discussion, it would appear that the d-c subcommittee should promptly seek similar information from other manufacturers and integrate it with the data of the report.

Fuller's discussion is similar to part of Baker's except that the average range of variation is not shown, undoubtedly on purpose, in order to focus attention entirely on the limits of variation in the test results. To get a true picture of the relative reliability of the test data, comparing the resistance method to the thermometer method, a thoroughgoing analysis should be made by the statistical methods used for modern quality control as suggested by Alger.

Stray Load Losses Measured in D-C Motors

AN AIEE COMMITTEE REPORT

THIS REPORT gives the results of tests to measure stray load loss made jointly by the Allis-Chalmers Company, General Electric Company, Century Electric Company, Reliance Electric and Engineering Company, and Westinghouse Electric Corporation on a motor exchange program at the request of the AIEE committee on rotating machinery. Motors tested ranged from 1/2 to 50 horsepower and were standard, open, general purpose, 40 degree centigrade, 1,750 rpm.

Stray loss measurements are reported for 27 load conditions covering three values of load current, three values of excitation, and three values of speed. The variation of stray loss with these variables is given for each of the motors tested. By averaging the data, assuming that the variables are independent of one another and of saturation and all other factors, a general formula is derived expressing the stray loss as a function of these variables. The tests are not considered conclusive although the average results are held to be significant.

Stray load loss in d-c machines is the sum of:

1. Additional core loss due to flux from windings excited by load current.
2. Eddy current loss in the armature winding caused by the periodic reversal of current flow in the armature conductors.
3. Component of brush friction loss which varies with load current apart from brush friction measured at no load.
4. Brush contact loss caused by imperfect commutation and by current conduction apart from the conventional contact loss calculated for constant voltage drop.

All but negligible sources of loss can be grouped under these four items. None of these items are directly measurable.

For many years the standard practice has been to include these losses in all efficiency calculations by taking them to be equal to 1 per cent of the output. If this allowance has not been as large as the actual losses in particular cases, prime movers driving d-c generators have been required to furnish more than the rated power or, in the case of motors, the current input has been higher than expected. When the allowance has been more than the actual loss the conditions have been reversed. Moreover, engineers have recognized that stray losses can vary quite widely from motor to motor depending upon design proportions and, in any given motor they do not usually vary in direct proportion to the output. Therefore, in making calculations for fuel economy for engine driven generators, or for overall efficiency of motor-generator sets or in calculating temperature rise, and in other calculations, engineers have not been satisfied with the 1 per cent rule. There has been a steady desire for some simple but more realistic formula.

Accordingly, the subcommittee on d-c machines of the AIEE committee on rotating machinery asked the five manufacturers to measure the stray loss of motors on a co-operative test program. Motors tested were rated 1/2, 5, 10, 25, and 50 horsepower, open, general purpose, 40 degrees centigrade, 1,750 rpm. Each company contributed a motor and each motor was tested by its manufacturer and by one other company, except for the 1/2-horsepower motor which has been tested only by its manufacturer. An exchange program was worked out to accomplish this.

The committee undertook the work recognizing that the present allowance of 1 per cent applies to machines of all sizes and to all conditions of load, that is, any voltage, any speed, any load current on any size and type of machine. This allowance can be correct only as an average. The departure from this average allowance as either the size of motor or the load conditions change is not known generally. Therefore, the committee undertook the tests to determine how well the 1 per cent allowance fitted the particular group of motors to be tested.

It was found from the average of all test data that stray load loss was 3 per cent of output. This holds at the average output of all the test conditions but was found to vary so that, for example, at the average rated full load output of the motors it was 2 per cent.

The results make it possible to devise a simple expression for stray load loss as in equation 5. In the future it should be possible to use such a simple rule with several values for the coefficient and exponent, each value corresponding to a group of machines. The several groups of machines would be divided according to size and type (for example, pole face windings or not). Therefore, an important result of the present tests is to show what may be accomplished by future extension and improvement of the work. Until this can be done the committee recommends that the present flat allowance of 1 per cent be maintained.

At the risk of confusing the reader, the results are given in both watts and per cent of output. This amounts to two ways of expressing one set of results. The formula for stray load loss, equation 5, can be derived from either the data expressed in watts or the data expressed in per cent of output. The derivation given starts

---

Paper 49-63, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 16, 1948; made available for printing December 21, 1948.

This report was prepared by the AIEE subcommittee on d-c machines of the rotating machinery committee.

Personnel of the AIEE subcommittee on d-c machines: T. M. Linville, *chairman*, Mrs. B. O. Buckland, W. E. Clancy, F. A. Compton, Jr., Lanier Greer, J. L. Hamilton, C. B. Hathaway, V. P. Hessler, V. B. Honsinger, W. R. Hough, P. Lebenbaum, C. Lynn, L. G. Opel, D. Ramadanoff, J. F. Sellers.

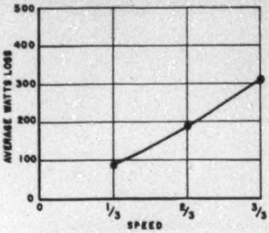

Figure 1. Watts versus speed

with the data in watts and ends by checking the formula against the data in per cent of output.

The reader is cautioned against attempting to attach importance to any single item of the data. Every engineer normally wants to feel that each element of a set of data is reliable and significant. But the committee feels that in this case the data must only be inspected in mass. When this is done the results have important value and real significance.

The discrepancy among the individual test results is a testimonial to the difficulty of measuring stray load loss. In future tests it will be helpful to extend the method to measure the loss of a machine twice, first driving it by the dynamometer and second driving the dynamometer by it. Moreover, it might be better to use two identical machines connected pump-back to read the total losses directly. Regardless of the method, large discrepancies are to be expected between the results of individual tests, because the brush loss due to friction and contact drop is subject to wide variations, and is commensurate in size with the stray load loss itself.

It has been suggested that the brush rigging be supported on bearings so that the friction can be measured continuously and that the brush contact voltage be read continuously through the use of an insulated brush. If this is done, a departure is made from the conventional definition of stray load loss which includes the vagaries of brush friction and contact loss as a part of stray loss. The committee believes that a great mass of test data is essential to find the general truth.

Method

In each test the power output of the motor was measured carefully with a dynamometer. The power input was measured by calibrated instruments. The difference between these two measurements gave the total losses of the motor. Total losses were measured in this way for 27 load conditions covering every possible combination of 1/3, 2/3, and 3/3 normal full-load speed, 1/3, 2/3, and 3/3 normal full-load flux, and 1/2, 2/2, and 3/2 normal full-load armature current.

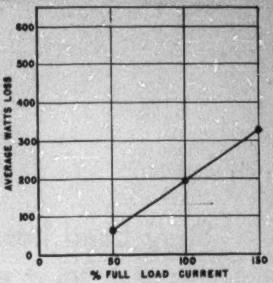

Figure 2. Watts versus current

The running light losses were measured directly by driving the motor from the dynamometer without armature current. Running light losses were generally checked by running the motor free of any connected load. Nine readings were taken by each method covering all combinations of speeds of 1/3, 2/3, and 3/3 of normal full-load speed and 1/3, 2/3, and 3/3 of normal full-load exciting flux. When the motor was driven electrically, the losses due to the input current were substracted from the input power. By these methods the running light losses comprising the loss due to bearing and

1/3 speed	86.1,	50 per cent current	60.7,	1/3 flux 174.3,	50 horsepower, 410.5
2/3 speed	183.9,	100 per cent current	191.6,	2/3 flux 210.6,	25 horsepower, 403.6
Full speed	313.3,	150 per cent current	330.7,	full flux 198.6,	10 horsepower, 98.0
					5 horsepower, 58.3
					1/3 horsepower, 0.18

*These data were taken at 1/3, 2/3 and full field current instead of 1/3, 2/3, and full flux

1/3 current = Approximately 39 per cent Flux

2/3 current = Approximately 75 per cent Flux

Full current = Full Flux

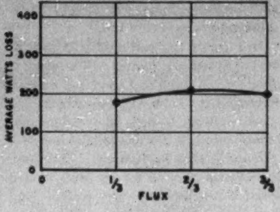

Figure 3. Watts versus flux

brush friction, the loss due to windage, and the open-circuit core loss were measured directly. The fact that the results gave smooth curves when plotted against flux and speed gave additional assurance of accuracy.

Copper loss for each load condition was determined by measuring the resistance of each winding, correcting it to the temperatures corresponding to each load condition, and multiplying by the square of the corresponding load current. Conventional brush contact loss was calculated for each load condition by multiplying the corresponding current by two volts for contact drop.

Stray load loss for each load condition was determined by subtracting from the total loss the sum of the running light losses, copper losses, and brush contact loss for the respective load conditions.

Results

Results expressed in watts are given in Table I. In Table II, the stray load loss is given expressed as per cent of motor output. Per cent of output is the recognized way of expressing the loss.

Because a general relation is being sought which will hold approximately for all conditions of operation and because error is expected in the stray loss measurement for each load condition, it is considered advantageous to average the results and to plot the average result as a function of each variable; that is, flux, load current, speed, and rated horsepower.

Figure 1 shows the average load loss in watts plotted against speed. The loss is proportional to speed raised to a power a fraction more than the first power.

Figure 2 shows that the average load loss plotted against load current varies about as the 3/2 power of current.

Figure 3 shows the average load loss plotted against flux, indicating some degree of independence of flux. It must not be imagined that the curve in this figure goes to zero loss at zero flux. If such were the case, the core loss determined by test under short circuit would be zero. If the load loss is truly independent of exciting field flux, then the losses under short circuit test which can be measured directly would give the true stray load loss when the corresponding brush friction, brush contact loss, and copper losses are subtracted from them. It has been recognized that short circuit core loss has some value as a measure of load loss. However, it cannot be calculated easily and no simple formula for it has been recognized any more than for load loss itself.

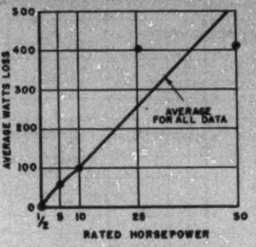

Figure 4. Watts versus rated horsepower

Figure 4 shows the average load loss for all of the tests on each motor plotted against the rated full-load horsepower.

1/3 current = approximately 39 per cent Flux
2/3 current = approximately 75 per cent Flux
Full current = Full Flux

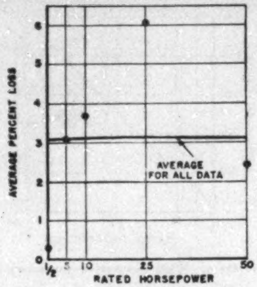

Figure 5. Loss versus rated horsepower

The solid line is drawn to have a slope determined by dividing the sum of the ordinates for all of the points by the sum of the abscissas.

Figure 9 is an enlargement of Figure 5. In this figure the heavy line represents the average result of 54 tests on each motor covering load outputs from 4 per cent of the rating to 150 per cent of the rating. The light lines in this enlargement show the wide variation of load loss as a percentage of output as measured in these tests. Tables I and II also show the wide differences in results.

Figures 6, 7, and 8 show the variation of load loss expressed as per cent of output with speed, load current, and exciting field flux respectively. These curves show average data obtained in the tests.

If, from inspection of Figures 1, 2, 3, and 4, it is assumed that the watts loss varies with the first power of the speed, with the 3/2 power of current, are independent of flux, and vary in proportion to the rated full-load horsepower, an expression for the dependence of the watts loss upon these variables may be established as follows

$$W=\frac{n}{n_r}\left(\frac{i}{i_r}\right)^{3/2} hp_r\, K \tag{1}$$

where

W = stray load loss at any operating condition in watts
n = speed of operation
i = load current
hp_r = rated full load horsepower
n_r = rated speed
i_r = rated full load current
K = constant factor

and if both sides of equation 1 are divided by the output load, *hp*, the resulting ratio of loss to output is

$$\frac{W}{hp}=\frac{n}{n_r}\left(\frac{i}{i_r}\right)^{3/2}\frac{hp_r}{hp}K \tag{2}$$

This ratio may also be expressed in terms of flux (the way it is shown in Figure 8) by substituting the following relation in equation 2

$$\frac{hp_r}{hp}=\frac{n_r}{n}\,\frac{i_r}{i}\,\frac{\phi_r}{\phi}\ \text{(neglecting part of the losses)} \tag{3}$$

giving

$$\frac{W}{hp}=\frac{\phi_r}{\phi}\left(\frac{i}{i_r}\right)^{1/2}K \tag{4}$$

where

ϕ = exciting field flux at output load
ϕ_r = exciting field flux at rated full load

The factor K can be evaluated from equation 2 using values which represent averages for all of the tests, that is, $W/hp = 0.03$ from Table II or Figure 5, $n/n_r = 2/3$, $i/i_r = 1$, $hp_r/hp = 9/4$, giving

$K = 0.02$

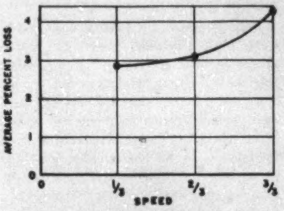

Figure 6. Per cent loss versus speed

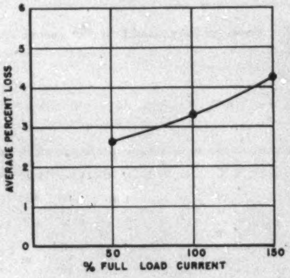

Figure 7. Per cent loss versus current

Therefore, the general expressions resulting from the average data are, from equation 2 and equation 4

$$\frac{W}{hp}=0.02\frac{n}{n_r}\left(\frac{i}{i_r}\right)^{3/2}\frac{hp_r}{hp}=0.02\frac{\phi_r}{\phi}\sqrt{\frac{i}{i_r}} \tag{5}$$

Equation 5 in either of its two forms may be used to check the curves of per cent loss versus speed, current, and flux as plotted in Figures 6, 7, and 8, respectively.

In Figure 6 the average loss of all tests at 1/3 speed are plotted. The same is done for 2/3 speed and also for 3/3 speed. Referring to Table II, the tests at 1/3 speed were made with all possible combinations of 1/3, 2/3, and full flux and 1/2, 2/2, and 3/2 full-load current. Therefore, the average flux, ϕ for the tests at 1/3 speed is 2/3 full flux, the average load current, i, is 2/2 full current, and hp/hp_r is 2/9 from equation 3. Substituting these values in either form of equation 5 yields $W/hp = 0.03$ or 3 per cent. For the tests at 2/3 speed the average values for flux, ϕ, and load current, i, are the same but now equation 3 yields $hp/hp_r = 4/9$. Using these values in equation 5 the answer again is $W/hp = 0.03$ or 3 per cent. Similar calculations for the average values at 3/3 speed give the same answer. Therefore, for comparison with the test results plotted in Figure 6, the calculated results using equation 5 are:

Speed	Per Cent Loss
1/3	3.0
2/3	3.0
3/3	3.0

In Figure 7, the average flux, ϕ, at each value of load current is 2/3 and the average speed, n, is also 2/3. By using equation 3 and the first form of equation 5 or by using the second form of equation 5 alone, the following calculated results are obtained for Figure 7:

Per Cent Current	Per Cent Loss
50	2.1
100	3.0
150	3.63

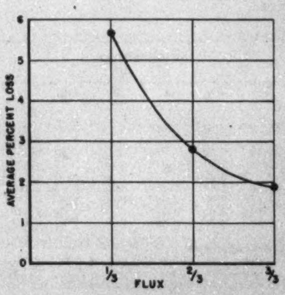

Figure 8. Per cent loss versus flux

In Figure 8, average values are, $n=2/3$, and $i=1.0$. Then from equations 3 and 5 the calculated results are:

Flux	Per Cent Loss
1/3	6.0
2/3	3.0
3/3	2.0

The general expressions of equation 5 may be used to check any of the test data in Tables I and II. By so doing any item of the test data may be compared with the result of the average "law," equation 5, derived from the mass of the data.

The mass of data summarized by the relations of equation 5 indicates that load loss is a fixed percentage of rated full-load output for the range of sizes tested but for fractional loads and speeds the loss varies in proportion to speed and in proportion to the 3/2 power of load current independent of exciting field flux. Although for the motors tested the mass of data indicates 2 per cent load loss at rated full load, it is certain that for very large motors the indicated percentage would be much less. Future work needs to be done to revise and establish general relationships similar to equation 5 so that the allowance for load loss for d-c machines can be specified in future standards on such a basis.

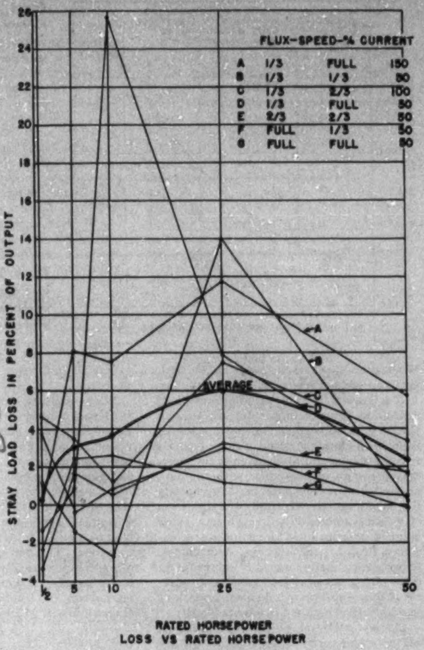

Figure 9. Enlargement of Figure 5, showing spread of data

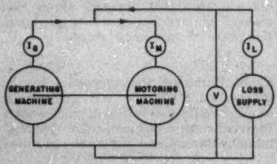
All tests in which either a maximum or a minimum occurred are shown. The points are averages of two tests for the 5-, 10-, 25-, and 50-horsepower motors, and one test for the 1/2 - horsepower motor

Discussion

B. H. Caldwell (General Electric Company Schenectady, N. Y.): This report presents interesting data and emphasizes the lack of adequate information on this subject. It also directs attention to the difficulties involved in getting accurate and consistent data.

It is well known that brush friction and brush contact drop both vary widely even under closely controlled operating conditions, and these factors make it difficult to repeat results. The variations from the normal might be expected to be great for a machine with a small number of brushes. Conversely for a machine with a large number of brushes the variation from normal might be expected to be smaller. Data accumulated from factory tests would seem to confirm this, since it has been found possible to get good measurement on large machines of load loss with the application of proper test procedures.

Figure 1. Pump-back connections for measuring total loss for two d-c machines



A direct measurement of total loss is to be preferred rather than measurement of input and output. The combined loss of two machines can be obtained readily from the relatively simple pump-back load test as shown in Figure 1 of the discussion. Here it is necessary only to meter the input current from the loss supply and the line voltage in order to compute the combined loss of the two machines. Other losses, having been predetermined by recognized methods, can be subtracted to give the combined stray load loss of the two machines. If the two machines are duplicate designs, then it is possible to assign the proper proportion of the combined load loss to each machine. It is only necessary to take account of the fact that the generating machine operates at the higher flux and the motoring machine operates at the higher armature current.

Data obtained in this manner are shown in Figure 2 of the discussion. The total loss was obtained by direct measurement. A number of tests were taken by different test crews over a period of several days. The points calculated from test data are indicated to show how well the data can be repeated. If other losses are calculated as specified in ASA, C-50[1] and subtracted from the total loss, resulting values of load loss as now defined are obtained. These values are plotted in Figure 3 of the discussion as curve 1.

A further refinement was added in the data plotted as curve 2 of Figure 3 of the discussion. The brush voltage drop was measured by using an insulated brush, and the brush drop loss was computed on this basis. Also the ohmic losses were corrected to apply at the measured temperature of the various elements. Two components which are normally included as part of load loss are thus eliminated. Variation of the brush friction loss from the value arbitrarily assigned is still included.

At rated load the load loss in this case is approximately 0.57 per cent. This compares with 2 per cent in the report and the present allowance in ASA, C-50 of 1 per cent. Similar data taken on large, compensated (pole-face winding) d-c machines shows the same general trends with load loss values which vary from a negative value of 0.09 to a positive value of 1.24 per cent at rated load. For variable speed mill motors in this class the load loss value is consistently higher at top speed than at base speed.

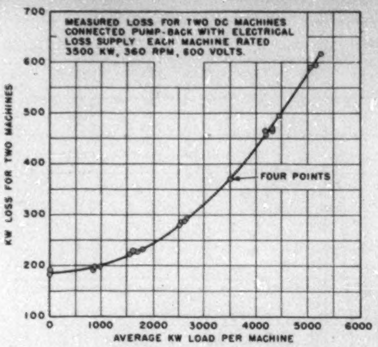


Figure 2. Loss for two machines versus average load per machine

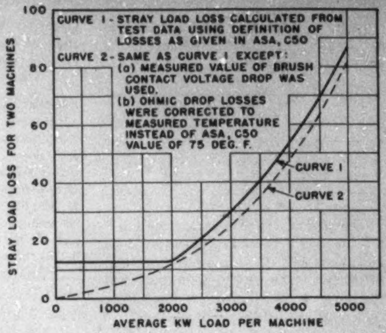

Figure 3. Stray load loss for two machines versus load per machine

With fixed speed there tends to be little variation of the load loss with change in flux.

It is known that the value of stray load loss is in general higher for an uncompensated machine than for a compensated machine. Thus, the value of 2 per cent for uncompensated machines given in the paper may prove to be consistent with the data presented here. It would seem appropriate to give serious consideration to modification of existing standards to recognize a lower value of stray load loss for compensated machines than for uncompensated machines. Other design factors are also important in determining the stray load loss, but the factor of compensation is a dominant one, and should be so recognized in our standards.

The committee should be encouraged to continue this project toward the end of accumulating sufficient data for intelligent revision of the existing 1 per cent rule. It is quite probable that the various manufacturers have considerable data available on this subject. The next step for the committee might well be to encourage the publication of these data.

In any further program for measuring stray load loss, a direct method of measuring the losses should be used. Various modifications of the pump-back method have been devised and described in the literature for doing this. The measurement so obtained is for two machines, so some uncertainty as to how the stray load loss should be divided is introduced. However, if the two machines are of duplicate design, the division of the losses can be assigned accurately.

1. Rotating Electrical Machinery. American Standards Association (New York, N. Y.), C-50-1943, 78 pages.

Edward Sand (Reliance Electric and Engineering Company, Cleveland, Ohio): Stray load loss tests taken at the Reliance laboratory in accordance with the method established by the subcommittee on d-c machines, showed the need of a better method of testing. Even after taking the tests several times in order to check the data, results showed that the stray load loss could vary over a wide range, depending on equipment accuracy and human error, because the value of loss which is small was obtained by taking the difference of two relatively large quantities.

When additional tests are to be made it is suggested that the Blondel opposition test method or some similar method be given consideration. This should reduce the testing errors as a percentage of stray load loss and give more consistent stray load results.

Essentially the Blondel method requires that the two identical machines to be tested be coupled together and to a small dynamometer to supply friction and windage and core loss. The two units are connected in opposition electrically with a boost-generator to supply the copper loss. More information on this method can be found in Direct Current Machinery.[1]

C. Lynn (Westinghouse Electric Corporation, East Pittsburgh, Pa.): We have made very accurate tests of loss measurements on larger size compensated d-c machines having low-loss type of armature winding and have found that under full field conditions the load loss may be only one-half of 1 per cent as compared to load losses of up to 3 per cent or even more, on small noncompensated machines. It should, therefore, be strictly understood that the information in the report applies to small machines of the industrial type, since the data are based on tests of motors from 1/2 to 50 horsepower only.

The pump-back method of testing if carried out accurately, particularly on large size machines, is very accurate and much better than using a dynamometer. When a dynamometer is used full power measurements are made and any inaccuracies in readings affect the results directly. By the use of the pump-back method with each machine operated at exactly the same air gap flux and using a calibrated motor connected to the two machines for supplying the mechanical losses of the two machines under test, which in turn are mechanically connected together and loaded back one on the other, and by supplying the electrical losses from a separate electrical source, very accurate data can be obtained.

It is, of course, understood that the brush friction loss decreases with load current. When machines are operated for long periods of time at light loads, a heavy film builds up on the commutator which causes high brush friction and can lead to chatter of the brushes. The flow of current to the commutator from the brushes prohibits too high a build up of this film, and due to the electrolytic action of this flow of current, easier sliding of the brushes on the commutator results. Therefore, the measurement of the brush friction at no load and no voltage is not a true measurement of the brush friction that results under loaded conditions. To obtain this it is necessary for the brush rigging to be mounted in such a manner that direct torque measurements on it can be obtained. This should be done in such a manner that no appreciable movement of the brush rigging results, because if this occurs the fit of the brushes on the commutator is disturbed and the results will no longer be accurate. In addition commutation may be affected.

The stray load loss is a compensation for practically every separate loss considered in figuring the efficiencies of a machine, because all of these losses are different under load than when measured under no load conditions. For instance the armature copper loss considers only the armature current squared times the resistance of the armature winding. This resistance is taken on the basis of 75 degrees centigrade copper which, of course, will not be the actual temperature of the copper throughout its length. This loss will be very different even in machines of the same size and having the same d-c armature resistance, depending on the arrangement of the conductors in the slot. Certain design features can reduce eddy current losses appreciably. Also, commutation introduces additional loss in those coils being commutated. The core loss obviously under load is entirely different than that obtained at no load under a prorated flux condition simulating that of the machine when loaded.

C. B. Hathaway (Westinghouse Electric Corporation, Buffalo, N. Y.): The purpose of this investigation was to determine what the relation the actual temperature readings taken by thermometer and the rise by resistance bore to the hot spot in open, industrial-type d-c motors is. This purpose has been accomplished. The results, however, have been somewhat disconcerting.

Little change in the standards appear needed for the open, continuously rated motor. It seems desirable to modify but one item. There should be a differential of 20 degrees centigrade instead of 10 degrees for the shunt field when comparing rise by thermometer and rise by resistance.

The story is quite different for the short-time rated motors. There are great discrepancies between the thermometer readings on the one hand and the rise by resistance and the hottest spot on the other.

The allowable temperature of the hottest spot for class "A" material could be adjusted upward to 120 degrees centigrade for 1/2 hour ratings, and to 140 degrees centigrade for 15-minute or shorter ratings.

The tests also disclose that on short-time ratings the rise by resistance is much more closely related to the temperature of the hottest spot than it is to the rise by thermometer. This lends weight to the contention that for short-time ratings the rise by resistance and the rise of the hottest spot could be the same.

While the tests show clearly that the temperatures present in the machines are much higher than indicated by thermometer readings, there is no evidence or experience that indicates that the old method of applying motors with short-time ratings established by the thermometer method provides motors inadequate for the application intended.

T. M. Linville: Stray load loss is one of those perennial subjects which one may want to elude but cannot. It affects the heating of a machine and must be accounted for by a manufacturer in working out the utilization of material, the internal temperatures, and the ventilation of machines. It may affect the power input or output of a d-c machine by several per cent especially under light-load operation. Therefore, it will continue to be a problem and a worthwhile thesis topic for college students without abatement. We can hope that the combination of test data and theoretical analysis will lead to a wider understanding of it.

With respect to an industry standard to allow for stray load loss, it seems the best we can hope for is to leave its determination to the manufacturer just as we now do for open-circuit core loss or else accept a standard allowance which is an average for all machines and perhaps fits none precisely. Stray load loss is a catch-all for the changes caused by load current in each of the normal components of loss. It follows no simple formula for any one machine, but when the loss in all machines at once is studied it does appear to follow a pattern which can be defined. This definition in simple form is what we are seeking for use as a standard. It requires many tests and the determination of average results.

Fortunately the discussors have brought out in each instance important suggestions regarding the method of test. These will be helpful for a continuation of the program. In planning the program of the paper, all persons concerned anticipated a variation in results of the order of 100 per cent or more even assuming nearly perfect accuracy in measuring the stray loss. This was because in many of the tests the brush-friction and brush-contact electrical losses which are highly variable were to be of the same order of magnitude as the stray loss itself and, therefore, cause the stray loss to be highly variable.

In all machines stray load loss should be recognized as an unstable item changing with conditions of operation and the length of time between change of conditions, being less stable for some machines than for others.

It was expected that by measuring the separate no-load losses accurately both by dynamometer and running light input methods and plotting the results as a function of speed, or field current as the case might be, that the error in these losses would be reduced to a negligible factor even considering the amplification of error due to the small remainder when these losses were subtracted from the total losses. The real question concerns the measurement of the total losses. Here we felt confident that the input and output could be measured using carefully calibrated meters and dynamometers under laboratory conditions, so that when the output was subtracted from the input the accuracy of the remainder would be good. Those who have made stray load loss tests in similar motors will recognize that there can be large variations in results regardless of the method used. Nevertheless, the best method should be used and our first choice for future tests would undoubtedly be one of the methods giving a direct measure of total losses.

It should be recognized that 243 stray load loss tests were made and in the charts showing average loss against rated horsepower each point except one is the average for 54 tests; also in the charts for average loss plotted against speed, or flux, or load current, each point is the average of 81 tests. The tests are not each of equal weight but their weights are smoothly graduated and the tests where the probability for error is the greatest are those of least weight. Therefore, it would appear that the average results are truly characteristic of the motors. For example, the over-all average of the 243 tests gave the load loss as 3 per cent of the output and simultaneously the average output for the 243 tests was 4/9ths of rated full load power. This is considered a true characteristic of these motors.

We know that if additional tests had been made on larger motors the stray load loss as a percentage of output would be less as the discussors point out. The factor 0.02 in equation 5 of the report would be less, or more certainly the form of equation 5 would come out differently to show the loss as a function of physical size in addition to the other factors appearing in the equation. Furthermore, a discontinuity would be expected at the point in size where machines become compensated by pole face windings. Since an exchange motor test program is not practical with large motors and since perhaps the manufacturers already have test data at hand which could be made available to the committee, it behooves the committee to seek these data. Until it is accumulated and its meaning determined it is, of course, not proper to consider any proposal for change of the present standard allowance of 1 per cent of the output.

Protection of Stations Without High-Voltage Switching

AN AIEE COMMITTEE REPORT

In recent years there has been considerable interest in the tapping of high-voltage transmission lines to serve various types of loads and the installation of the transformers on these taps without high-voltage circuit breakers. The necessity to supply war loads with a minimum use of material provided a great incentive in this direction. Also, the present high costs of construction have increased the desirability of this type of installation.

It is well-known that the omission of the high-voltage circuit breakers complicates the problem of providing adequate relay protection for the line and the transformer tapped on the line. In some cases, the omission of high-voltage circuit breakers on tapped transformers makes it impracticable to obtain adequate line protection without the use of carrier-current or pilot-wire relays.[1] Protection for the tapped transformer requires tripping the high-voltage line circuit breakers which may be several miles distant from the transformer. Various methods are in use at the present time to accomplish this function.

In order to obtain information on the types of protective systems being used for the protection of stations without high-voltage circuit breakers, the AIEE relay committee has reviewed the practice being followed by the industry in this type of station. A questionnaire has been circulated covering the principal items under consideration, and answers have been received from a large number of representative companies from various parts of the United States and Canada. The answers received from these companies have been recorded in Table I. Various companies submitted detailed diagrams of their installations, and these have been grouped into the representative types shown in Figure 1. The stations without high-voltage circuit breakers can be classified into two categories; stations that are tapped to high-voltage transmission lines; and stations at which high-voltage lines are terminated without the use of a high-voltage circuit breaker.

The survey was limited to installations where the primary voltage was 66 kv or higher and involved those stations that have no form of local protection, such as a circuit breaker or a fuse.

Summary of Information Received

QUESTION NUMBER 1

How many stations without high-voltage switching are installed and how long have they been in service on your system?

Practically all companies answering the questionnaire indicated that they had some installations of stations without high-voltage switching. The 25 companies reporting had 169 installations, some of which had been in service up to 25 years. This would indicate general acceptance of this method of supplying substation loads and terminating high-voltage lines in order to obtain economical installations.

QUESTION NUMBER 2

What types of transformer protection are used for these installations?

The answers to this question agree substantially with the report presented in 1946[2] by the relay subcommittee on the

Summary of the Questionnaire Which Was Circulated

Question Number

1. How many installations of stations without high-voltage switching, and approximately how long have they been in service on your system?
2. What type of transformer protection is used for these installations?
3. What methods, if any, are used to trip the remote high-voltage line circuit breakers for trouble at the local station without high-voltage switching?
4. What size transformers are installed?
5. What is the largest size transformer that would be installed on your system without high-voltage switching?
6. What are the distances from the point where the station is located to the adjoining circuit breakers?
7. If an automatic grounding switch is used for protection, what is the time required for its operation?
8. If remote trip is used, describe the method. If pilot wire is employed, are the wires owned or leased?
9. If a reclosing system is employed on the high-voltage line, does the remote trip system lockout the reclosing procedure?
10. Experience Data: what has been your experience with this type of installation? Describe cases of failure if any have occurred.

Paper 49-65, recommended by the AIEE relay committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 8, 1948; made available for printing December 23, 1948.

This report was prepared by the project committee of the AIEE relay committee, power group.

The personnel of the project committee consists of: E. L. Michelson, *chairman;* L. F. Ferri, L. L. Fountain, V. J. Hayes, R. A. Larner and K. N. Reardon.

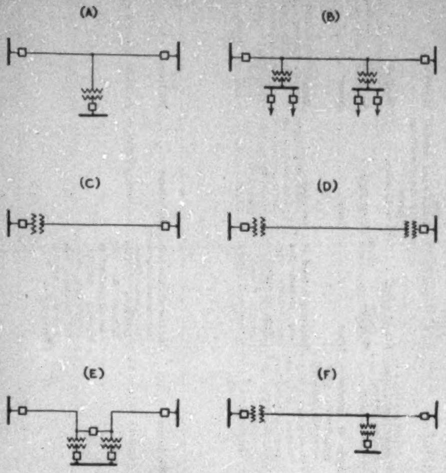

Figure 1. Typical stations without high-voltage switches

status of transformer protection. Various methods are used, depending upon the size of transformer and other considerations. In most cases, transformers of large size are equipped with differential relays. It should be noted that not all of the methods listed for each company are used on each installation.

QUESTION NUMBER 3

What methods, if any, are used to trip the remote high-voltage line circuit breakers for trouble at the local station?

The answers to this question indicate use of various methods to trip the remote line circuit breakers for trouble at the station without high-voltage switching. In 69 installations out of the total 169, there is no special method, and the only protection consists of the relays at the main terminals of the line, which are used primarily for line protection. On the remaining 100 installations, the methods used to produce remote tripping consist of special grounding disconnect switches or remote-trip relay schemes which function either through pilot-wire or carrier-current systems. These methods are described in more detail under a later question.

QUESTION NUMBER 4

What size are the transformers?

It was indicated there is practically no limit to the size of transformer installed without high-voltage switching, installations up to 100,000 kva being reported in this survey. Other cases up to 180,000 kva are known.

QUESTION NUMBER 5

What is the largest transformer that would be installed without high-voltage switching?

In most instances it was indicated that there was no definite limit.

QUESTION NUMBER 6

What are the distances from the point where the station is located to the adjoining circuit breakers?

The answers to this question indicated that distance was not an important factor, since such distances ranged from 100 feet to 100 miles.

QUESTION NUMBER 7

If an automatic grounding switch is used for protection, what is the time required for its operation?

The principle of the grounding switch is comparatively simple. It consists of a special disconnect switch arranged for high speed closing, with the closing circuit initiated by the protective relay used on the transformer without a high-voltage circuit breaker. When the grounding disconnect closes, it places a solid phase-to-ground fault on the transmission line, which permits the line relays at the main terminals of the line to de-energize the entire line. Closing times of six cycles to two seconds were reported, most of the installations being about 15 cycles.

QUESTION NUMBER 8

If a remote trip is used, describe the method. If pilot wire is employed, are the wires owned or leased?

The remote-trip schemes are based on the use of either pilot wires or carrier current. The use of pilot wires is comparatively simple, but the cost of pilot wires is the principal disadvantage of this scheme. Where pilot wires are used, the scheme generally consists of initiating a d-c signal by the differential or other relays that are used to protect the station without high-voltage switching. This d-c signal is received at the line terminals and provides for the tripping of the main circuit breakers. One advantage of this scheme is that high-speed tripping can be obtained safely by this method.

In some cases, separate wires are used for this function, but in many cases the d-c signal is superimposed on wires that are used for other purposes.

Where pilot-wires are used, there is no general agreement on the use of owned wires or leased wires, both being used.

On longer transmission lines the remote-trip function is accomplished by the use of carrier-current signals. Many special methods are being used at the present time to accomplish this function.

The principal problem in setting up a remote trip circuit by carrier current is to provide safe operation, considering the possibility of false signals being introduced into the line due to lightning, arcs at the terminals due to switching, and other causes.

One method for preventing false tripping which has been used successfully is to provide one signal which is on the line continuously and blocks the remote-trip function. In order to set up the remote trip circuit, it is necessary to shut off this blocking signal and introduce a tripping signal.

Another method is to use time as a factor by requiring that the remote trip signal be on for a period of time. The possibility of false operation is thereby reduced considerably.

In some cases it is necessary to consider the tapped transformer as a line terminal, with the result that a more elaborate relay scheme is required to obtain adequate system protection. This may mean carrier-current blocking equipment at the tapped installation (to prevent tripping the remote circuit breakers for low-voltage faults) or full carrier-current relay equipment if simultaneous fault clearing is necessary in order to permit automatic reclosing. Transformer faults then are cleared by adding to the carrier-current relaying scheme a remote trip function. In the case of short lines a

Table I. Summary of Protection of Stations Without High-Voltage Switching

Question	Company Number 1	Company Number 2	Company Number 3	Company Number 4	Company Number 5	Company Number 6	Company Number 7	Company Number 8	Company Number 9
1	20 stations—average nine years per station	6 stations—1 to 13 years	1 transformer bank, in service 11 years	1 station, in service seven years	4 stations—years not given	26 stations—up to 25 years	4—installed during war years	12 stations up to 18 years	None at present—had one in service 4 years
2	Banks under 5,000 kva: Overcurrent at remote ends—banks over 5,000 kva:—Differential, low-oil level low-oil pressure, and high temperature	Varies with stations—use combinations of: Differential - overcurrent-low oil-temperature	Differential and overcurrent	No protection (radial system)	Varies with stations—use differential ground, reactance, overcurrent, pilot wire, and carrier relays	High side fuses, thermal relays, overcurrent and differential relays	Carrier relays on terminals of line—distance relays on terminals of line and distance relays directional to bank on low side—differential relays which operate grounding switch	5 stations no protection; others have overcurrent relays	Differential relays
3	Single pole grounding switches closed by differential relays	4 stations—single pole grounding. One special case—phase to ground (Used because of ground fault neutralizer)	Current pilot wire relay scheme	Remote circuit breakers are not tripped for low-voltage faults	Pilot wire and carrier	Single pole grounding switches	None, except one station that has single pole grounding switch which is closed by differential relay	No remote tripping scheme	Automatic ground switch
4	1,000 to 20,000 kva banks	5,000 kva to 10,000 kva	40,000 kva	3,000 kva bank	30,000 kva to 75,000 kva	12,000 to 20,000 kva	9,000 kva to 12,000 kva	2,000 kva to 12,000 kva	15,000 kva
5	Size not considered a limiting factor	Do not know	Do not know	Do not know	No limit set (Based on using remote tripping)	No fast rule	No set standard	Transformer capacity not governing factor	15,000 kva
6	6 to 65 miles	6¼ to 26 miles	3.1 miles	6 to 12 miles	8 to 11 miles	60 miles (using fuse) 5 miles (others)	4 to 61 miles	5 to 15 miles	50 miles
7	30 cycles	9 to 12 cycles	None used	None used	None used	15 cycles or less	20 cycles	None used	15 cycles
8	Not used	Not used	Owned pilot wires	Pilot wires leased	Owned and leased pilot wires. Owned coaxial cable	None at present—proposed pilot wires will be owned	None	None	None
9	When 20 cycle reclosing employed. Carrier current relay signal is used to lock out reclosure. For normal automatic reclosure, the 1st reclosure delayed enough for transformer to be disconnected automatically by high voltage air break switch	Not used	Not used	Not used	Not used	Yes	Reclosing is used at one station—but no remote trip. None on others	Not used	None
10	No cases of failure	Experience satisfactory. No incorrect operation. One case where a grounding switch fell closed due to defective latch	Two cases of insulator failures which operated transformer differential relay and remote circuit breaker was properly tripped	No failures	No failures except two tripping operations due to double grounds on pilot wires in substation. Rectified by use of separate pilot wire battery	No failures	One transformer failure caused lockout on terminal circuit breakers. Two failures of tap change mechanism caused shorting switch to close, far terminal line circuit breaker tripped	No failures	No trouble

Question	Company Number 10	Company Number 11	Company Number 12	Company Number 13	Company Number 14	Company Number 15	Company Number 16	Company Number 17
1	3 stations—up to 22 years	10 stations, from 1 to 17 years	4 stations, from 1 to 17 years	2 stations from 2 to 7 years	15 stations from 1 to 19 years	5 stations—(years omitted)	16 stations from 15 to 20 years	2 stations, about 77 years
2	Use overcurrent, differential, directional overcurrent, and directional distance	Overcurrent, reverse overcurrent differential, thermal, reverse magnetizing, high-low oil; high-low gas, directional ground, and modified directional impedance relays in conjunction with carrier	Directional overcurrent, distance, directional overcurrent phase and ground, differential, ground, and pilot wire relaying	One station: percentage differential other: —differential ground and directional overcurrent. Oil temperature and gas pressure relays operate signal only	Overcurrent or directional phase and ground relays at source end of line; or differential relays	Differential relays	No local protection—protection obtained by overcurrent relays at remote line	Differential — directional distance—Overcurrent Phase and Ground—directional ground
3	One station none, one station pilot wire, other station carrier	Carrier with audio tones	For three stations tripping of remote high-voltage circuit breakers not initiated by local transformer relays. One station uses pilot wire for transfer tripping	Transfer trip via pilot wires at one station—carrier to be installed at other station	None. Depend upon line relaying at remote high voltage circuit breakers	Carrier—pilot wire—single phase grounding	Not used	Depend on directional distance protection at the far end
4	15,000 kva to 25,000 kva	7,500 kva to 67,000 kva	30,000 kva to 100,000 kva	24,000 kva to 50,000 kva	4,000 kva to 37,500 kva	7,500 kva to 40,000 kva	Largest—14,000 kva	25,000 kva
5	Probably 30,000 kva	80,000-kva auto transformer	Approximately 50,000 kva	Not known	Would not hesitate on size	No limit	No limit established	No limit established
6	3 to 28 miles	5 to 66 miles	5 to 15 miles	7.7 to 10.7 miles	5.4 to 41 miles	9.5–48.7 miles	Few miles to 20 miles	20 miles
7	None used	None used	None used	None used	None used	Not measured	Not used	Not used
8	Pilot wires leased—one station; —method is directional comparison by carrier directional distance relays plus carrier code transferred trip when low-tension circuit breaker opens on transformer differential	Remote trip uses carrier frequency plus audio tones of 150 and 208 cycles. The differential relays on the transformer energize an auxiliary lock-out relay, which in turn, trips the local circuit breaker and sends out the remote trip signal to the distant source terminal	Use pilot wire monitoring and transferred tripping relays on leased pilot wires	Owned pilot wire	None	Use 2-tone audio signal superimposed on carrier and time delay relay—also single-tone audio signal without time delay. Also leased pilot wire polarized d-c. Relay at remote end	None	None
9	Reclosing is manual, but hand reset lockout relay operated by remote trip warns operator not to reclose	Yes. The automatic reclosing on the local circuit breaker is locked out; and the receiving of a remote trip signal at a distant source locks out the automatic reclosing on the high-voltage line at that location also	Automatic reclosing not used—but the transferred tripping scheme locks out the closing circuits of the remote circuit breakers	Not used	Not used	Reclosing scheme is used only in case of automatic grounding switch and it is not lock-out	Not used	Not used
10	One failure on low side transformer leads operating differential relays and correctly operating remote trip. Two cases of incorrect operation of transformer differential relays resulting in operation of remote trip	No actual transformer failure calling for operation of remote trip. Two false trippings believed due to disturbances in the d-c supply to carrier audio tone transmitters and receivers causing trip signal to be sent out. Filters to be installed to prevent such disturbances	One case of trouble of high-voltage bushing flash-over on 30,000-kva transformer. Fault cleared by ground relay at remote end of line	No failures	Satisfactory — only two transformer failures	Several incorrect operations with tone - modulated carrier scheme	Satisfactory	Good—no failures of protective equipment

2	Overcurrent relays; differential at one installation	Overcurrent at one station and overcurrent and differential at other	Overcurrent and differential	Differential	Overcurrent and differential	Differential, overcurrent, gas detector	Differential relays	Impedance and ground relays
3	Carrier plus backup relays. Also overcurrent relays	One station: single pole grounding switch actuated by differential relay	Carrier and pilot wire	Grounding disconnect	Grounding disconnect	Ground 1, 2, or 3 phases; relay on remote-end line protection	3 stations use transferred-tripping over relay pilot wires	Impedance and ground relays
4	30,000 kva to 60,000 kva	25,000 kva to 45,000 kva	45,000 kva to 100,000 kva	10,000 kva to 41,000 kva	15,000 kva to 52,000 kva	4500 kva to 50,000 kva	30,000 to 100,000 kva	30,000 kva
5	No limit	Unknown	100,000 kva	Not known	No limit	No set limit	100,000 kva	Would not install in future
6	20 to 90 miles	33 to 40 miles	3 to 52 miles	3.5 to 9 miles	1 to 27 miles	100 feet to 100 miles	5 to 15 miles	70 miles
7	None at present—to be installed on one bank—11 cycles	Instantaneous	Not used	Spring operated; 6 and 12 cycles, motor operated 2 seconds	18 cycles	Approximately 1 second	Not used	Not used
8	None at present—but under consideration	None	Radio frequency carrier current relaying with 3,000-cycle modulation trips the remote ends of the lines after 1/4-second delay. Also differential relays initiated the transfer trip by increasing the direct current transmitted over the owned differential pilot wire system	None	None	Not used at present. A carrier current remote trip scheme used for a while was not satisfactory	Superimposed direct-current over leased pilot wires used for a-c pilot wire relaying	Not used
9	None at present	Not used	Not used	Not used	Not used	No, permit one reclosure. Prefer delaying reclosure long enough for transformer to be disconnected automatically by motor-operated disconnects	Not used	Not used
10	Very good	Good—no failures	One case where relay in remote trip circuit failed to make contact. Routine tests also indicated: defective tubes in carrier radio equipment—3 cases faulty operation of relays—minor trouble in communication channel units. Some trouble in maintaining constant current in monitoring relay and pilot circuit, cause undetermined	Satisfactory	Satisfactory	Satisfactory. Motor-operated grounding switches more reliable than spring operated switches	No adverse experience	Satisfactory but residual currents at far end for ground faults near high-voltage side of transformer are too small for positive relaying

pilot wire scheme may be used to accomplish the same results.

Question Number 9

If a reclosing system is employed on the high-voltage line, does the remote trip system lock-out the reclosing procedure?

At the present time, reclosing systems are not generally used, as indicated by this survey. In those cases where reclosing is used, various schemes are employed. In some cases there is no lock-out system and the line is permitted to reclose on the fault. If the fault is in the transformer, or is some other type of permanent fault, the relay system will function to reopen the line. In other cases, a lock-out scheme is employed and the remote trip signal is used to prevent automatic reclosing.

In one case, the protective relays automatically open the transformer disconnects at the tapped station, and reclosing is permitted to take place within two seconds after the first opening.

Question Number 10

Experience data.

Practically all companies reported satisfactory experience with this type of installation. Some trouble has been reported with the remote-trip carrier schemes. The general opinion obtained from most companies would indicate that stations without high-voltage switching can be operated and protected successfully.

Discussion

V. J. Hayes (Connecticut Light and Power Company, Waterbury, Conn.): This report would indicate that, in general, satisfactory experience with this type of protection can be obtained. Out of the 25 companies reporting on a total of 169 installations, four found cases that could be considered as incorrect operation which might make desirable a change in the original design of the remote tripping scheme. One of these was on a pilot wire system where double grounds occurred. This type of trouble is not difficult to detect, and in the case reported a remedy was devised for it. A second company reported one case where a relay in the remote trip circuit failed to make contact. The other two companies reported difficulties which were associated with audio-tone-modulated carrier systems. One of these two attributed the false tripping to variations in the d-c supply to the audio-tone-trip signal transmitter and receiver units. It is possible that the operation of d-c equipment, such as motors, on the same source as the carrier sets caused a ripple in the d-c voltage containing frequencies that were within the operating range of the audio-tone-trip signal units. Filters to prevent such disturbances are mentioned as a remedy.

Another possible source of incorrect operation in tone-modulated carrier systems is due to beat frequencies caused by two or more simultaneous carrier frequency signals on such a system. Trouble is not likely to occur if two audio frequencies are used to supervise the remote tripping circuits, but field tests have shown that single audio-tone receivers will operate when the two or more simultaneous carrier frequencies produce a beat note within the operating range of that receiver. This can probably be avoided by separating the carrier frequencies employed on that system by an amount so that the combination of their nominal separation and drift in frequency of the individual carrier sets does not produce a beat note within the operating range of the audio-trip signal units.

J. A. Elzi (Commonwealth and Southern Corporation, Jackson, Mich.): We are all vitally interested in methods of accomplishing desired results as economically as possible without sacrificing reliability or introducing undue complications. This frequently calls for a great deal of ingenuity and study to make sure that the simplification used does this without introducing unforeseen hazards. A survey of actual field experience such as given in this report is therefore of very great interest and importance to the industry.

This report deals primarily with the protection of stations with particular emphasis on the protection of the power transformers at these stations. A recent AIEE paper on Relay Protection of Power Transformers[1] indicates that where switching equipment is provided for power transformers, differential protection is the generally accepted method of clearing transformer faults and that very few transformers are protected only by other back-up relays. In contrast to this, it is noted that out of a total of 169 installations without high-voltage switching, 69 provide no special method of protecting the transformer and the only protection consists of the relays at the main terminals. It would seem that we have unduly sacrificed transformer protection in stations without high-voltage switching. This may be due to undesirable features of available schemes of protection, a lack of reliabliity, or excessive costs.

Of the 100 installations that reported the use of some means of remote tripping, the special grounding switches seem to be used most frequently, and they also seem to indicate the greatest degree of reliability. There are, however, some very definite objections to placing a fault on a transmission line in order to clear a fault in a transformer. Also the time required to clear a transformer fault by this method is somewhat longer than by other methods so that this method cannot be said to give as good protection as would be provided by some of the other methods.

A few installations of remote tripping over pilot wire are mentioned and the answers to Question Number 10 indicate that some trouble has been experienced with this type of protection. This is not surprising in view of the very low current used for tripping in many of the pilot wire schemes. For example, one scheme requires only $1^1/_2$ to 2 milliamperes with a maximum of 5 milliamperes available for tripping, and another scheme requires 6 milliamperes for tripping with only 8 milliamperes available. Considering the number of cases of trouble reported compared with the number of installations reported as using the pilot wire remote tripping scheme, it would seem that there is a real need for improving this type of tripping scheme.

Under Question Number 8 the authors mention some of the possible causes of incorrect tripping when carrier current is used to provide the remote trip function. If we interpret this survey correctly, there are four of the reporting companies now using some form of carrier signals for remote tripping, and three of these reported trouble. Two companies have such equipment under consideration. One company reported that a carrier current remote trip scheme which was used for a while was not satisfactory and has been removed from service. The report therefore seems to definitely indicate that we do not have a reliable and satisfactory scheme of providing remote trip by carrier signals. The authors mention the introduction of time delay as a means of overcoming some of these difficulties. The length of time required is not given, but it can be seen that the introduction of appreciable time delay is very undesirable from the standpoint of providing adequate transformer protection.

It is felt that the statement made in this report under Question Number 10 is too optimistic and gives a false sense of security. Those companies using no remote tripping scheme are not providing transformer protection comparable to that provided where high-voltage switchgear is used. The line grounding switch seems to be the most dependable and reliable but introduces a certain amount of time delay and is somewhat undesirable inasmuch as it introduces a fault on the line. The pilot-wire and carrier-current remote trip schemes which would provide transformer protection comparable to that obtained with high-voltage switching are not shown to be very reliable by the report and should be made the subject of further study.

1. Relay Protection of Power Transformers, AIEE Committee Report. AIEE Transactions, volume 66, 1947, pages 911–16.

Chester E. Bauman (Harza Engineering Company, Chicago, Ill.): It probably is beyond the intended scope of this report to include the problem of stability in connection with low-voltage switching of transmission lines. We have found stability to be the important consideration. In one specific case where a large hydro was located 145 miles away, it was necessary to clear all "2-line to ground faults" on the lines in 0.1 second. This would not allow time for using any kind of short-circuiting switch on the transmission line. In fact, we found that the large change of transfer reactance occasioned by switching out the transformer at both ends along with the transmission line resulted in instability.

In one case where we employed low-voltage switching with transfer tripping operated by transformer differential relays, we experienced trouble due to automatic battery charger at one end causing false operation of transfer tripping. The exact cause of the trouble was not determined, but replacement of the automatic charger by a motor generator set eliminated the trouble. If similar trouble has been experienced by any other engineers, their comments will be appreciated.

E. L. Michelson: In Bauman's discussion he points out one of the limitations of the type of transmission line discussed in this report. The committee study did not encompass a study of the various applications of the tapped transmission line. While there are some limitations in its use, actual experience indicates that there are many instances where it is economical to install taps on high-voltage transmission lines.

All of the discussors point out the difficulties which have been experienced in setting up a reliable remote tripping scheme. We agree that this is one of the present limitations in the protection of tapped transmission lines. Undoubtedly, there will be further developments in this field, and improvements made in carrier-current and pilot-wire systems, to insure more reliable operation. The AIEE relay committee expects to continue its study of this subject and promote interest in the development of improved methods of remote tripping.

In the matter of tripping time for transformer faults, there appears to be some difference in opinion as to the need for very high-speed protection. While there obviously are advantages to 1-cycle protection under all conditions, on the other hand, no system difficulties may be experienced if protection for a low-voltage system, or a transformer, is delayed for a few cycles. The damage caused by a low-current fault may not be sufficient to justify very elaborate schemes to obtain 1-cycle operation.

Electronic Relay Developments

JAMES J. LOVING, JR.
MEMBER AIEE

THE NEW advances in electronics accelerated by the recent War offer many applications in addition to their use for military, aviation, or communication purposes. This paper describes briefly the results of some experimental and development work on the application of electronics to electric power system protective relaying. Heretofore, the use of electronic circuits in relaying schemes has been mainly as a supplement to the more conventional electromagnetic schemes, as for examples, the use of carrier current in a pilot directional scheme and auxiliary electronic relays for timing, and so forth. The purpose of the development work described here has been twofold—first, to apply the newer techniques to the fullest advantage and second, to employ electronic circuits so as to perform complete relaying functions in themselves.

The advantages offered by these electronic relay circuits as developed and compared with electromagnetic types or prior electronic types are as follows:

1. The number of moving parts and contacts has been reduced to an absolute minimum by having all functions of fault detection, determination of direction and distance, insertion of intentional time delays, and so forth, performed by the electronic elements, so that the only moving elements required are those in the actual tripping, indicator, and alarm circuits. A small mechanical relay is operated by the final output tube if circuit breaker tripping is required.

2. With a few minor exceptions, the circuits are constructed of standard electronic parts, the only special work required being the construction of a suitable chassis or housing unit and a few special windings on transformers.

3. A high degree of accuracy is obtainable in the determination of overcurrents, in the measurement of distances to faults, and in the insertion of intentional time delays. The characteristic curves are very flat throughout the operating range for such functions as fixed time delays, reach of distance elements with varying voltage and current, and operating time in the first zone of a distance relay application.

4. The sensitivity of the vacuum tube elements provides proper action with very low system voltages, and they respond during the first cycle of fault.

5. The only magnetic parts involved are the cores of radio-type transformers and consequently there are no adverse effects due to magnetic saturation as sometimes occur in electromagnetic relays when the fault current has a long d-c transient. The energy required for actuation of the electronic elements is very small, resulting in small burdens on potential and current transformers.

6. All vacuum tube circuits place very light loads on the tubes, with the development centered around the use of the *6SL7* and *6SN7* types, so that reliability and long tube life can be expected with the use of a minimum number of tube types.

7. In a carrier current relaying scheme, electronic elements can furnish directional control of the carrier channel, with actuation of the transmitter and utilization of the received signal being performed electronically. Since the transmitter can be turned on at very high speed, it is not necessary to start carrier by a distance element and stop it by a directional control, but rather the carrier transmitter is actuated by a distance-directional element responsive only to faults in the reverse direction. This allows very high speed tripping for internal faults.

The principal disadvantages of these electronic circuits stem from the fact that they depart considerably from standard relay practice in the past:

1. In the development, particular attention was paid to attaining reliability, but this remains an unknown factor until such time as extended tests in actual operation can be made.

2. Electronic applications are relatively new in the utility industry and in particular, relay operating engineers and maintenance men are not generally acquainted with electronic techniques.

3. The internal wiring is somewhat more complex than the electromagnetic equivalent, but this is probably compensated for by the simplification of the external wiring.

4. As at present developed, the circuits depend upon standard station battery of 125 volts for heating vacuum tube filaments and furnishing positive d-c potentials, and place a slight additional drain on these batteries.

5. Although built-in test switches can furnish a quick means of testing the functioning of all tube elements, periodic tests or replacements at fairly long intervals would still be required.

General Principles

In Figure 1 is a 1-line diagram of a section of a transmission line which illustrates the manner of applying electronic relays for protection of the line against faults. Electronic relays can be constructed for any type of relaying required and in most cases the relaying for phase faults would fall into one of three classifications: directional overcurrent, distance directional, and carrier current. The type of ground fault protection would be co-ordinated with the phase fault protection. Thus, a 3-phase electronic directional overcurrent inverse time-delay relay and an electronic ground directional relay could supply overcurrent protection for the line. Or a 3-phase electronic distance-directional relay with one, two, or three zones could supply faster tripping for the greater length of the protected line and back-up for the other zones. For best fault location and highest speed, electronic relays could be provided for furnishing directional control in a carrier current relaying scheme.

In Figure 2 is a block diagram illustrating the general method used with a

Figure 1. Application of electronic relaying to transmission line protection

3-phase electronic relay connected to a line through a set of potential transformers and a set of current transformers. Since the electronic elements are voltage actuated, the line currents are not utilized directly but are carried through the primaries of small coupling transformers included within the electronic relay, and the outputs of these transformers are used to reproduce the line currents. In order to make a comparison of phase and polarities of the line currents with other system conditions, such as the line voltages, the reproduced current waves are converted into series of sharp voltage pulses by electronic pulse forming circuits.

The pulses are first applied to fault-type detector circuits whose main function is to insure that the proper currents and voltages are compared in order to provide correct relaying. They are then applied to functional elements, such as directional and distance elements, with control voltages derived from the protected line. If these functional elements determine the fault to be within the protected section, the pulses are allowed to pass to an impulse circuit for actuating the tripping circuit. The dotted sections indicate that there are complete elements for each phase of the protected line and also there may be elements for ground protection. The actions of all the phases are combined in the impulse circuit. In Figure 2, the positive pulses sketched at the output of the pulse-forming circuits may be passed by the fault-type detector circuits as shown by (a) or they may be blocked or clipped as shown by (b). Similarly, the functional elements may pass the pulses as in (c) or block them as in (d). This description applies to any relaying scheme where instantaneous action is desired, but in overcurrent relaying with inverse time delay or in zone-type distance relaying, intentional time delays must be inserted to provide sequential operation. The method of applying inverse time delay is illustrated in Figure 3. In addition to actuating the pulse-forming circuits, the outputs of the current coupling transformers are rectified to provide a d-c voltage proportional to line current flowing. This d-c voltage provides a tripping impulse after a delay inversely proportional to line currents provided that the functional elements of the relay determine the fault to be in the tripping direction. The delay action is thus directional controlled.

Where zone type protection is desired, the relay can be constructed as in Figure 4. Here there is a separate distance element for each zone of the protected line, and for the second and third zones fixed delay circuits are provided which are actuated only if the fault is within the particular zone. A fault in the first zone will operate the impulse circuit directly, but a fault in either of the other two zones will provide tripping only after the fault has persisted in that zone for a predetermined time period.

The method of combining electronic relaying with carrier current so as to provide an all-electronic directional controlled carrier relaying scheme is illustrated by the block diagram of Figure 5. Here a distance-directional element responsive to faults in the tripping direction actuates the impulse circuit. This causes circuit breaker tripping unless prevented by the blocking circuit controlled by the carrier current received from the remote end indicating that the fault is external to the protected section. A second distance-directional element responsive only to faults in the reverse direction actuates the carrier transmitter for preventing tripping at the remote end. Since the actuation of the transmitter is at very high speed, tripping for internal faults can also be at high speed since it is not necessary to turn on the transmitter in case of internal faults.

Figure 7. Fault-type detector circuit

Pulse Forming Circuit

In order to provide a means of comparing the phase and polarity of the currents and voltage on a line so as to determine at high speed the direction and distance to a fault, the line current wave is converted into a series of sharp voltage pulses by the circuit shown in Figure 6(a). This circuit also serves as a means of detecting overcurrents and of providing phase shift in the current response of the relay when necessary. The secondary line current flows through a small coupling transformer and for a current wave form as shown in (b), the voltage output of this transformer leads the line current by 90 degrees as in (c). The phase-shifting circuit of R_1, C_1, R_2, and C_2 provides a voltage proportional to line current and approximately in phase with it as shown by (d). Electronic amplifier *V-1* is normally biased to cut-off and the time constant in the primary of the output transformer is made short so that the output of the amplifier will be a series of pulses as shown in (e). These are positive when the input voltage exceeds the cut-off level of the tube and negative when this voltage drops below cut-off. In place of the combination of current transformer and coupling transformer, it would be possible to use an air-core transformer in the line with output direct to the phase-shifting circuit.

Figure 6. Pulse forming circuit

For use in an electronic overcurrent relay, the values of R_3 and R_4 providing positive cathode bias are selected so that utilization of the full output of the coupling transformer will provide pulses for a predetermined minimum line current, or in other words, the cathode bias determines the maximum sensitivity of the relay. The potentiometer at the output of the coupling transformer can be calibrated directly in terms of secondary line current.

For use in an electronic distance relay, the potentiometer is omitted and proper characteristics obtained by inserting a suitable phase-shift, as explained later in discussion of the distance element. The operating range in the phase overcurrent relays is 4-to-200 secondary amperes and in the distance and ground relays, 1-to-200 amperes. Greater sensitivity for the ground relays can be obtained by the use of taps in the coupling transformer.

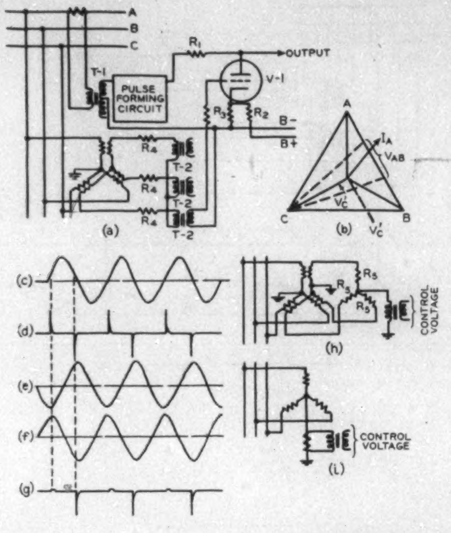
The time constants R_1C_1 and R_2C_2 are both short when compared with the time constant of a normal d-c transient in the line current wave, and it can be shown mathematically that the response of the phase-shifting circuit will approach the steady-state after approximately one-quarter cycle, so that in the first peak the overswing of the transient is virtually eliminated. A transformer-coupled amplifier is used rather than a resistance-coupled amplifier so that fluctuations in battery voltage will not appear at the output.

Fault-Type Detector Circuit

In some applications it is necessary that the pulses caused by a particular line current be blocked from action in the relay unless the line current is due to a particular type of fault. One method of accomplishing this is demonstrated by the "fault-type" detector circuit of Figure 7(a).

The pulse-forming circuit is responsive to the line current in A phase so that pulses are produced for either an A-to-B fault or an A-to-C fault as shown in graph (e). These pulses are applied to the anode of *V-1* through resistor R_1 and the grid of *V-1* is controlled by a voltage proportional to (I_B-I_C) and shifted approximately 90 degrees ahead, this voltage $V_{(I_B-I_C)}$ being obtained from the coupling transformers associated with B-and-C phases through combining resistors R_3 and R_4.

For the case of an A-to-B fault as illustrated in the vector diagram (b), the voltage $V_{(I_B-I_C)}$ is negative at instants of the positive pulses as shown by graph (f)



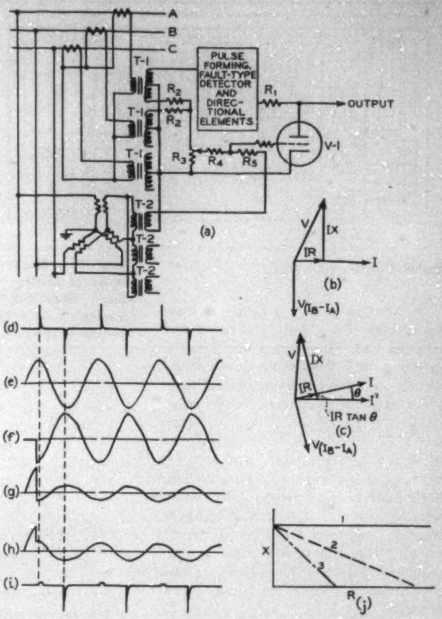


Figure 8 (left). Directional element

Figure 9 (right). Distance element

so that *V-1* is nonconducting at the instants of the positive pulses and they appear at the output. For the case of an A-to-C fault in the vector diagram (c), the control voltage as shown in (g) is positive at the instants of the positive pulses so that *V-1* is conducting and the pulses are dissipated through R_1 and the tube, and the output pulses are "clipped" as shown in the graph (h). This circuit performs correctly with or without load current in the line, as the fault current normally predominates over load current.

In order to allow the pulses to pass for the case of a 3-phase fault in the vector diagram (d), the capacitor *C* provides sufficient phase-shift in the control voltage

An alternate method of providing a response to an A-to-B fault but not to an A-to-C fault is to actuate the pulse-forming circuit by a voltage proportional to $(I_A - I_B)$ and to block the pulses by a voltage proportional to $(-I_C)$ and pass them by a voltage proportional to $(-I_A)$, this method requiring tube two elements instead of one.

For applications requiring ground preference relaying, a similar arrangement can be utilized with the control voltage actuated by ground current so as to block the pulses due to phase currents. Also the fault-type detector circuit can be applied to relaying involved in a single-pole reclosing scheme.

Directional Element

The circuit of Figure 8(a) demonstrates a directional element, with A-phase fault current as shown by graph (c) producing pulses as in (d). A voltage in phase with delta voltage V_{AB} is obtained by shifting the opposite star voltage V_C ahead 90 degrees, as shown by V_C' in vector diagram (b) for an A-to-B fault, and is accomplished by air-gap transformers *T-2* Y-connected through resistors R_4 to the secondary potentials. With a fault in the tripping direction, the control voltage (e) allows the positive pulses to pass, and with a fault in the reverse direction the control voltage (f) blocks or clips the pulses as shown in graph (g). Resistors R_2 and R_3 provide bias for *V-1* and this is adjusted so that with zero control voltage, the pulses are just blocked sufficiently to prevent relay action, thus obtaining high sensitivity.

If the pulses due to I_A are controlled by a fault-type detector circuit responsive only to an A-to-B fault, the action of this directional element will be correct no matter at what instant a fault occurs, as the current from phase A-to-B is caused by V_{AB} and will never turn positive when V_{AB} is negative. In the case of an A-to-C fault it is possible for I_A to be positive at the first instant of fault when V_{AB} is negative, so that without a fault-type detector circuit the arrangement cannot be used except where a slight time delay for tripping is allowed.

The opposite star voltage is used rather than using the delta voltage directly for two reasons. In case of dead short circuits, V_{AB} falls to zero whereas V_C retains full value. Also, it has been experienced that any coupling transformer of reasonable size utilized to reproduce the delta voltage directly will not drop to zero immediately at its secondary side if the primary voltage drops to zero, whereas with the phase-shifting arrangement as used, the time constants are so short that responses are accomplished in sufficient time.

For directional control in electronic ground relays, one method is as shown in (h), where three equal resistors R_5 are Y-connected, furnishing a voltage at their common point to ground proportional to the system residual voltage. This is coupled to the relay by a radio-type transformer, and the arrangement is possible because of the negligible energy

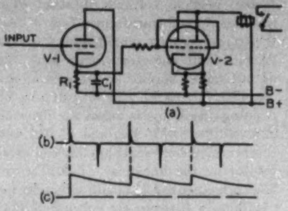

Figure 10. Impulse and tripping circuits

required. An alternate method is shown in (i) where the control voltage is obtained by causing the neutral current of a source of ground current to flow through a coupling transformer.

In the phase relays, by using the opposite star voltages, correct action is obtained for dead short circuits in either direction. For 3-phase faults, three-quarters volt rms (secondary) is required per phase to obtain tripping. In the ground relays, due to the gain in the coupling transformer, only one-third volt residual is required for tripping.

Distance Element

For determining distance to a fault, the phase-to-phase delta voltage is compared with the corresponding delta current. The method for doing this is illustrated in Figure 9(a). The pulses caused by A-phase line current are passed through fault-type detector and directional elements to determine if the fault is from A-to-B phases and in the tripping direction. A comparison is made between the A-B delta voltage on the line obtained from one of transformers *T-2* with a voltage proportional to (I_B-I_A) obtained from equal combining resistors R_2 and shifted ahead 90 degrees. This comparison is made by resistors R_4 and R_5 and the differential or balance voltage so obtained applied to the control grid of *V-1*. Graph (d) shows the pulses due to line current, (e) the delta voltage and (f) the voltage proportional to delta current. If in the balance voltage, the current predominates as in (g), the pulses will be passed to the output but if the voltage predominates as in (h), the pulses will be clipped as in (i). The distance setting is controlled by potentiometer R_3.

If the pulses are produced at the instants the line current passes through zero, the voltage $V_{(I_B-I_A)}$ proportional to (I_B-I_A) acts against the reactive component of the delta voltage as shown by vector diagram (b), so that the distance element acts as a reactance relay as indicated by curve 1 in Figure 9(j). If the pulses are produced after the current passes through zero as though the current were I' in Figure 9(c), the voltage $V_{(I_B-I_A)}$ must be slightly greater than the reactive component by an amount equal to $IR \tan \theta$. Or in other words, the reach of the distance element is reduced to $(X-R \tan \theta)$ resulting in the characteristic curve 2 of Figure 9(j). The distance measurement at the first instant of the transient is the reactance to the fault, as the delta voltage is compared with the rate of change of current. For 3-phase faults, the pulses are produced 30 degrees later resulting in the 3-phase fault characteristic of curve 3 in Figure 9(j).

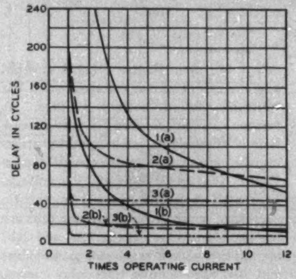

Figure 12. Characteristics of time-delay circuits

Since the fault currents are at low-power factor and load currents normally at high-power factor, the effect of load currents on the reach of the distance element is small.

The distance elements require that the protected line be of sufficient length to provide three secondary volts rms for minimum current faults at the far end of the line. The range is from 0.1 to 20.0 secondary ohms.

Impulse and Tripping Circuits

If any phase of a relay determines that circuit breaker tripping is required, the pulses are allowed to pass to an impulse circuit, as shown by *V-1* in Figure 10(a). Pulses applied to the grid of the tube cause capacitor C_1 to charge quickly through the tube and upon removal of the pulse, C_1 discharges slowly through cathode resistor R_1. The pulses as shown in (b) are thus converted into a series of decaying d-c voltages as in (c). This d-c voltage is then applied to tripping tube *V-2* for actuation of the plate circuit relay for tripping.

Time Delay Elements

For obtaining an inverse time delay, the circuit of Figure 11(a) is used. A rectified voltage proportional to a system current is obtained from *V-1*(a) as shown in (c) for the line current in (b). This d-c voltage is applied to capacitor C_1 through variable resistor R_1, but the voltage across C_1 is normally held at a low value by *V-1*(b). Upon the occurrence of predetermined fault conditions, the associated relay produces a negative voltage as shown by (d) which is applied to the grid of *V-1*(b), thus allowing capacitor C_1 to charge as in (e). The time delay circuit is thus functionally controlled, and after a time inversely proportional to

Figure 13. Laboratory version of electronic ground directional relay with inverse time characteristic

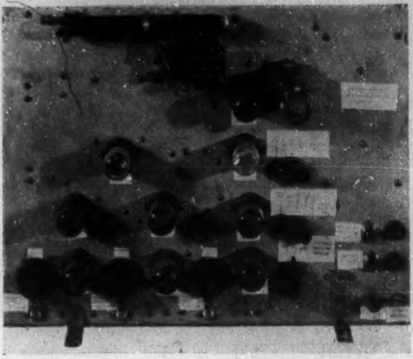

Figure 14. Laboratory version of 3-phase distance-directional relay

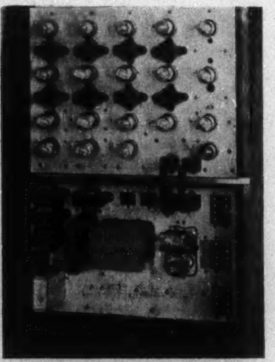
Figure 15. Model of electronic carrier current relaying for one terminal of transmission line



system current *V-2* becomes conducting. Upon removal of the fault, C_1 rapidly discharges through *V-1*(b) and allows quick reset of the tripping and timing circuits, this being accomplished in from three to six cycles even after very long delays.

In order to provide a fixed definite time delay, *V-1*(a) in Figure 11(a) is omitted and the source of d-c voltage used is the constant station battery voltage. A further variation resulting in very inverse time characteristics is obtained by utilizing the output of impulse circuit *V-1* in Figure 10(a) as the source of d-c voltage. Figure 12 shows the time characteristic curves, in which curves 1(a) and 1(b) are the typical inverse curves, 2(a) and 2(b) are typical very inverse curves and 3(a) and 3(b) fixed definite time delay curves. All of these are for short delays, with longer delays about four times as great obtainable for each type.

Complete Relay Models

A number of models have been constructed with Figure 13 showing a laboratory version of a ground directional relay and Figure 14 a 3-phase distance-directional relay. The application of electronic relaying to an all-electronic carrier relaying scheme has been accomplished in the model shown in Figure 15.

The schematic wiring diagram of a ground directional relay with directional controlled inverse time delay is in Figure 16. The relay is actuated by residual or ground current flowing through *T-1* and system residual voltages obtained from resistors R_{24} and transformer *T-5*. *V-1*(a) is a pulse forming circuit and *V-2*(a) a ground fault detector circuit with the output pulses applied to directional element *V-2*(b). If the ground fault is in the tripping direction the pulses are inverted and rectified by *V-3*(a) and *V-3*(b) and this negative d-c voltage applied to *V-4*(a) for starting the time delay. *V-4*(b) serves as an amplifier and *V-1*(b) as a rectifier for obtaining a positive d-c voltage proportional to ground current and for charging capacitor C_6 through variable resistor R_{18}. Tripping tube *V-5* conducts after a time delay inversely proportional to ground current, and upon clearing of the fault, *V-4*(a) becomes conducting again and C_6 discharges rapidly, thus allowing quick reset of the tripping circuit.

Figure 17 is schematic wiring diagram of a 3-phase distance-directional relay for protection of the first or instantaneous zone of a transmission line. The three secondary currents flow through transformers *T-1* and actuate elements for each phase of the relay. The center horizontal row of tubes is typical of the action in which *V-1*(b) serves as a pulse-forming circuit and *V-4*(a) as a fault-type detector circuit. The directional element is provided by *V-4*(b), the distance element by *V-5*(a), and for a fault within the protected section the pulses are allowed to actuate impulse circuit *V-5*(b) which in turn causes tripping tube *V-9* to operate the line circuit breaker. The tripping time for the majority of faults is one to two cycles, depending on the point in the voltage cycle at which the faults occur. The distance-directional characteristics of this particular relay are shown in Figure 18, the average tripping speed for faults at various locations in Figure 19 and a typical reactance characteristic in Figure 20.

In Figure 21 is a schematic wiring diagram of a 2-zone distance-directional controlled carrier relay including ground fault protection, in which the top row of tubes is typical of the phase action and the bottom row supplies ground protection. *V-1*(a) serves as a pulse-forming

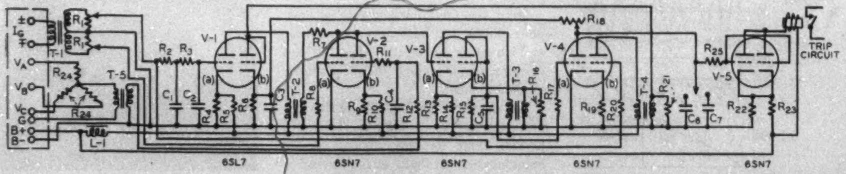

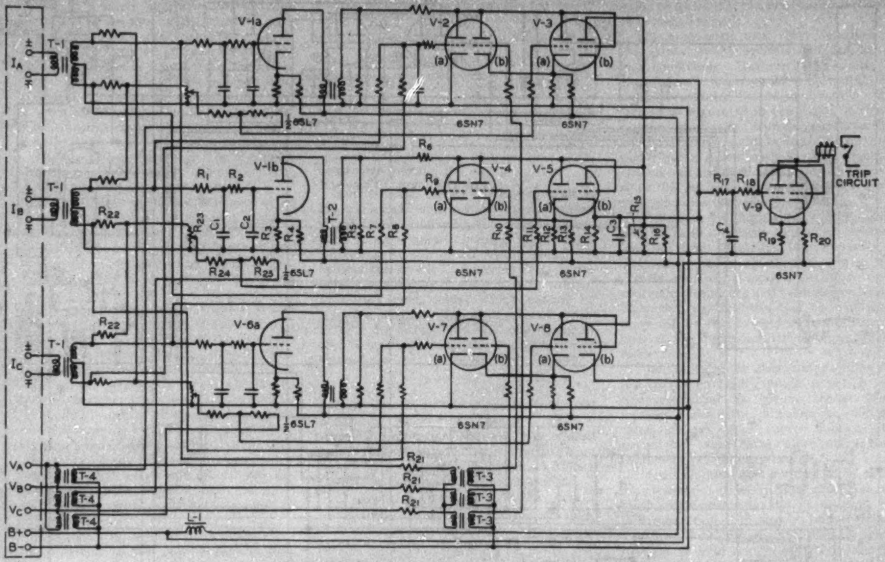

Figure 17. Schematic wiring diagram of 3-phase distance-directional relay

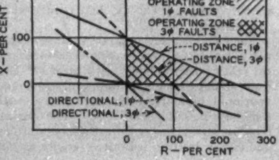
circuit, V-2(a) as a fault-type detector circuit and V-2(b) and V-3(a) the directional and distance elements respectively, for faults in the tripping direction. An impulse circuit V-3(b) causes circuit breaker tripping by V-16 if the fault is in the tripping direction and there is no received carrier from the remote end of the protected line. V-4(a) and V-4(b) furnish the directional and distance elements for faults in the reverse or blocking direction and actuate impulse circuit V-14(a) which in turn actuates the carrier transmitter by V-18. V-17 causes blocking of the tripping impulse if the fault is in the reverse direction or if there is a received carrier signal. In case of internal faults, tripping action is initiated in one-half to one cycle.

Figure 18. Tripping characteristics of distance-directional relay

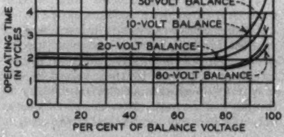


For simplicity, the foregoing wiring diagrams do not show details of the tripping, indicator, and alarm circuits used on the models, which are conventional. Test switches provide means for testing the function of all electronic elements in a very short period without the use of auxiliary equipment. These remove the electronic elements temporarily from their connections to the current coupling transformers and apply voltages to the elements simulating various types of faults.

Filaments are connected in series through a suitable dropping resistor, with each filament shunted so that in case of burn out of one tube the others will remain in use.

In addition to the detailed circuits shown, tests have been made on phase overcurrent directional-relay circuits with inverse or fixed time delays, zone-type distance-relay circuits and a simplified carrier relay using overcurrents for fault detection.

Figure 19. Operating time of distance-directional relay

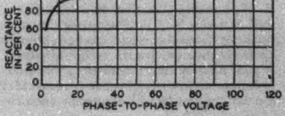


The models have all been tested on the miniature line shown in Figure 22 and have had intermittent laboratory duty for six months, including a 2-months continuous duty run, with no false operation or failures. Other extensive tests, such as effect of change in battery voltage on performance, effect of changes in tube characteristics, and so forth, indicate that no serious troubles should result from unusual operating conditions.

Conclusions

The development work described in this paper indicates that electronics can be utilized to obtain improvements in the

Figure 20. Reactance characteristic of distance-directional relay



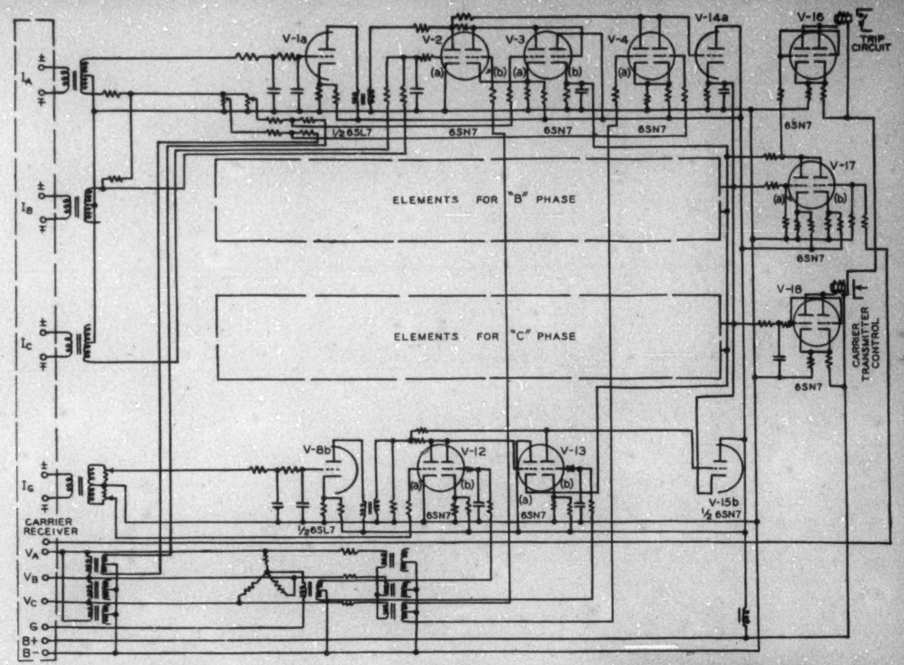


Figure 21. Schematic wiring diagram of electronic 2-zone distance-directional controlled carrier current relay including ground fault protection

accuracy, speed, and co-ordination of protective relays. By the use of standard electronic parts in their construction, the elimination of external auxiliary equipment and the provision for calibration by simple potentiometers, the electronic relays afford opportunities for savings in cost and simplification of maintenance. They require a minimum of tube types and are well suited to using ruggedized tubes; based on tube manufacturers' data and operating experience with other electronic equipment in utility applications, an average tube life of three to five years can reasonably be expected. Their versatility makes them adaptable to any relaying scheme by the combination of functions into integrated units or by simple circuit changes to obtain desired characteristics. In the development of the relay circuits, consideration was given to making them as nearly independent as possible of the uncontrollable factors that might be encountered in use, so that optimum performance would be obtained at all times.

---

Discussion

H. W. Lensner (Westinghouse Meter Division, Newark, N. J.): The use of electronic tubes for protective relays has been brought up from time to time in technical papers. It is of interest that practically every function now performed by a mechanical relay can be duplicated with electronic tube circuits. The general acceptance of electronic relays, however, depends on their advantages over equivalent mechanical relays.

The protective relays now in use represent years of development which have produced a device that approaches the ultimate in performance as proved by their record in use. It is not enough that an electronic relay do the job just as well. It must offer features not to be found in mechanical relays such as speed, burden, accuracy, and reduction in maintenance.

For example, it is claimed that electronic relays are faster in operation than mechanical relays. The curves of Figure 19 show time values that might well apply to a conventional high-speed distance relay, with tripping times of a cycle or so. The over-all tripping and reclosing time of a modern relay and circuit breaker is limited largely by the inertia of the circuit breaker mechanism and the de-ionization time of the arc path, and it seems that little increase could be made in the stability limit of a power system by paring a fraction of a cycle from the relay time. Electronic relays have no inertia, it is true, but the inertia of a mechanical relay is often of advantage in riding through a short transient on which it would be undesirable to trip.

The use of delay filters in the a-c input circuits may solve the problems of preventing false tripping on transients.

There is a limit to the possible speed of an electronic directional element as it may require nearly half a cycle to determine the direction of power flow. One apparent advantage of an electronic directional element is its ability to trip at high speed with very low a-c voltages.

The use of electronic protective relays always raises the questions of tube life and maintenance. The advent of the "ruggedized" tubes with a minimum life of 10,000 hours is one answer to this question. There still remains such problems as tube heater supply, battery drain, and failure alarm. A remote substation with perhaps dozens of mechanical relays requires a minimum of relay maintenance, and a station battery with a very low steady drain used primarily for tripping. With electronic relays, the demand on the battery is increased, and some alarm system would be desirable in event of tube failure.

It is too early to judge the value of electronic relays. A few years of field service, with ultimate improvements resulting from the experience gained, may put electronic relays in a prominent position for consideration in power system design.

Stephen V. Hart (Industrial Electronics, Inc., Detroit, Mich.): Loving's paper is impressive in that it demonstrates how those results in protective relaying which were heretofore achieved by electromagnetic means, can be achieved by electronic means. The circuit technique used, incorporates many features which were developed during the war for radar use. Attention is drawn to the pulse-forming circuits which make 1-cycle operation possible.

The usefulness of these circuits could be broadened if the following four steps were undertaken:

1. *Fail-safe Operation*

As they stand, many of the circuits would not indicate, by themselves, failure of tubes or associated components. It is believed that acceptance in practice will depend on the safety and reliability of these circuits. Redesign is advocated which will cause automatic alarm indication (or tripping of circuit breaker) should any vital component fail.

2. *Achievement of Novel Results*

The use of electronics opens the way to new applications in the power relaying field. It is not so much a matter of duplicating the performance of present electro-magnetic devices, but rather a step beyond, to achieve results not achieved heretofore. As an example, the over-current relay could be made sensitive to the slope of the initial transient, and could thus differentiate between a condition which may cause generators to fall out-of-step, and a fault which is within stability limits.

3. *Omit Conventional Transformers*

Often the current and potential transformers are the weakest link in the relaying system. By use of electronic amplification the use of the conventional types can be avoided. Air-core, toroidal transformers, and capacitive dividers are but two of many possibilities.

4. *Miniaturization*

The use of standard-size tubes has advantages, and the specialization on two tube types is desirable from the stockkeeping and replacement view point. However, the use of the mechanically more rugged miniature tubes and sub-miniature tubes should be considered, which, together with the latest miniaturization techniques would result in very compact and light-weight design. This would undoubtedly increase the appeal of the electronic relay to the power companies.

Summarizing, Loving's painstaking effort has introduced much of the latest thinking into the power relaying field and is an important step toward making these relays acceptable to the public utility field. To achieve this end it is suggested that the inherent possibilities of electronics be utilized to obtain new results which cannot be achieved electro-magnetically, and while making the circuits fail-safe, one may proceed to make the design more compact; this should provide a better relay at less cost.

John B. Gmeiner (The Commonwealth and Southern Corporation, Jackson, Mich.): A relay application engineer has several points to consider when he is applying a relay to perform certain functions. Among those to be considered are the following:

1. What burden will the device impose on the current and potential transformers?
2. If external continuous energy is required to operate the device, what are the requirements?
3. Will the relay give proper performance under heavy load conditions?
4. Will the relay perform accurately for repeated operation between maintenance and calibration periods?
5. If inverse time delay is involved, how will the relay characteristic curves coordinate with other relays and protective devices such as fuses?
6. If the relay is a distance-type relay, how well do the distance measuring characteristics perform the required job?
7. What special problems of maintenance are likely to be encountered?
8. What are the switchboard requirements?
9. What is the cost?

These are all questions that must be answered adequately before a relay is recommended for a particular application. How does the electronic relay as described by Loving fulfill the requirements listed above?

It is desirable that a relay does not impose more than a 1-ohm burden on a current transformer. The author indicates the burdens are low. While the input impedance of the various tube circuits described is probably in the thousands of ohms, with proper usage of matching input transformers, the reflected burdens on the current transformer and potential transformer circuits are probably low. It would be a helpful addition to the paper if specific values had been stated.

It is hoped the coupling transformers to the current circuit have been designed so they will not saturate when subjected to fault currents which may range from 50 to 100 amperes.

Most of the present-day relays do not require an external source of energy which is certainly desirable. What is the maximum value of watts that the electronic relay may be expected to use?

The overcurrent-type relay described in this paper should perform well for heavy load conditions. However, load ability of the distance relay would have to be examined carefully before application. Referring to Figure 18 in the paper, it would appear from the 3-phase characteristic curve, tripping might be initiated for high power factor heavy loading. It is assumed that second and third zone elements are used since this is the accepted practice for complete distance-type phase protection.

With the use of high quality circuit components and recently developed selected long-life radio tubes, the characteristics of electronic relays should not vary too greatly over any 6-months period between routine maintenance and calibration checks. However, it is doubtful that the electronic relay will be able to hold the calibration as well as the corresponding electromagnetic relay.

Upon plotting the characteristic time delay curves on log-log graph paper, it was discovered that the curves labeled "very inverse" had a rather flat slope beyond two times pickup. The curves labeled "inverse" were considerably more inverse than the ones labeled "very inverse." It would be desirable to have another time delay characteristic curve with a more inverse slope approaching that of a fuse curve.

Examination of Figure 18, tripping characteristics of distance-directional relay, brought to light several points of interest. The reach is quite different for phase-to-phase and 3-phase faults. This is a condition that is not desirable. Allowing for arc and transmission line impedance it may be seen that on a 3-phase fault, the relay will give coverage of only 60 to 70 per cent of the first zone setting. The straight line characteristic of the impedance relay will be susceptible to power swings which could cause unnecessary tripping. It would be more desirable to have an impedance circle or better yet an offset circle characteristic for the electronic relay.

The speed with which the electronic relay will operate has been stressed. Modern relays now operate in one or two cycles for first zone functioning. Due to transients and lack of necessity, it is doubtful whether faster operation than this is desirable or necessary.

With carrier current relaying becoming prevalent in most of the larger utility systems in this country, operating personnel are becoming acquainted with electronic equipments. Therefore, no great additional training of personnel should be necessary in the average application of this relay to provide proper maintenance. However, from past experience with electronic equipment, it is expected that more maintenance for electronic relays will be encountered than for a comparable electromagnetic relay.

From the illustrations in the paper, the space requirements of the relay appear to be somewhat less than for other types of relays. This might be true especially for the carrier relaying scheme.

It is to be hoped that these and other problems may be solved and the electronic relay can offer improvements over present relaying schemes. With further developments, the relay may be able to perform functions not now possible by present-day relays. Any new device meets a good deal of resistance in the field before widespread acceptance is made of that unit. Undoubtedly this will be the case with the new electronic relay. At the present time there are years of experience behind the development and application of electromagnetic relays. They are rugged and reliable in operation. Their limitations and capabilities are well known. The electronic relay does not have this background and will have to have several years of field use before its reliability is proved. However, the electronic relay should be a welcome addition in the field of relaying, especially if it shows advantages in performance, costs, and space requirements, and it is hoped that its use will fulfill the expectations of the author.

James J. Loving, Jr.: The discussers have raised a number of questions which were not adequately covered in the paper in order to hold it to reasonable length.

Lensner points out that the speed of operation of the electronic relay circuits as indicated by the curves of Figure 19 do not improve appreciably over the time characteristics for electromagnetic relays. In the final tripping circuit of the distance relay to which the curves apply, an intentional time delay of one cycle was inserted, so that the ultimate speed attainable by electronic relaying is greater than that shown by the curves.

The intentional delay was inserted because there is the possibility of false operation due to transient response of the coupling transformers for a small percentage of faults without the delay. In the case of application to carrier relaying, there is no possibility of failure to apply carrier in sufficient time, so that the very high tripping speed of one-half to one cycle is attainable. Also, the speed of response is relatively independent of system voltages, as is brought out by Figure 19.

The use of electronic relays would place an additional drain on station batteries, and if *6SL7* and *6SN7* tubes were used, this drain per relay would be in the order of 0.6 to 0.8 amperes, or about 75 to 100 watts. This additional battery load might be offset by the smaller requirements on potential and current transformers.

Gmeiner suggests that more specific values of burdens be stated. In the models constructed, the burdens on current transformers are about 0.2 volt-amperes per phase at normal current, and on potential transformers about 3 volt-amperes per phase for each function of the relay placing load on the potential circuit. The loading is due to the coupling transformers required, as the actual loading by the vacuum tube circuits is negligible. The small current coupling transformers used contain an air gap and show no indication of saturation at currents of 40 times normal.

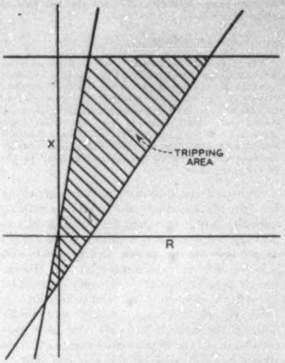

Figure 1. Tripping area enclosed by straight lines in electronic relaying circuit

Due to lack of data as to reliability, electronic relays would undoubtedly require more frequent maintenance checks until reliability is proved. However, the use of special built-in test switches could provide a means of checking very quickly whether all tubes were functioning properly. These switches place control voltages on the tube circuits similar to those encountered during a fault and thus no external test equipment is required except for re-calibration. The distance elements in the electronic circuits should hold their calibration even better than electromagnetic relays, as the comparisons of voltage and current magnitudes are made by simple resistor networks before application to the tube circuits.

The time delay characteristics and distance characteristics given in the paper are by no means the only ones obtainable by electronic circuits. It is possible to enclose any desired tripping area on the R–X diagram for a distance-directional relay by straight lines. In Figure 1 of the discussion, for example, the tripping area shown could be obtained by a relay constructed of a pulse forming circuit, a blocking circuit for each straight line of the area, and a tripping circuit. Also, it is possible to make the response to 3-phase faults identical with the response to single-phase faults by the addition of a separate set of tubes responsive only to 3-phase faults.

Hart mentions the desirability of designing the circuits so that a component failure would give an alarm indication. This could be done quite easily for the case of open-circuited tube filaments, but might be quite difficult and expensive for other component failures. The question of the reliability of the miniature-type tubes as against the normal size ruggedized tubes is one which could be settled only by trials with the different types. The electronic relaying circuits could undoubtedly be designed around the miniature tubes if this should prove more desirable.

It is probably possible to build an electronic relay which responds to the rate of rise or slope of the current during a fault or out-of-step condition. Some experimental work indicates that a circuit can be devised which duplicates the envelope of the current wave and then acts according to the relative steepness of the envelope.

There are possibilities in the simplification of current and potential reproducing devices over those now employed for electromagnetic relays. In the circuit of Figure 6 in the paper, an air core toroidal transformer placed around the line conductor could replace the current transformer and coupling transformer insofar as the need of a current transformer for an electronic relay is concerned.

Similar possibilities exist for simplification of potential circuits.

The discussers of the paper have made valuable comments and their interest is appreciated.

Rectifier Fault Currents—II

C. C. HERSKIND

C. E. RETTIG
NONMEMBER AIEE

A NUMBER of modes of circuit action may be obtained during faults on power rectifiers because of the variety of fault conditions and circuit parameters. Analyses of some of these have been treated in a previous paper.[1] This paper presents a further extension of this work with analyses of a number of idealized cases. An analysis is presented for the transient fault current during d-c short circuit and a procedure is outlined for analyzing the fault currents during arc-back with both a-c and d-c feed.

The objective of these studies is the development of a comprehensive procedure for the analysis of the circuit action and the determination of fault currents in rectifier circuits during d-c short circuits and arc-back. A complete treatment of the fault currents obtained in the widely used 6-phase double-Y circuit is particularly desired.

The results of fault current calculations and tests on a 200-kw 300-volt scaled ignitron rectifier equipment are compared. The wave forms and magnitudes of the fault currents obtained under various test conditions are shown by oscillographic records.

Data are presented showing the nature of the rectifier arc-drop at fault current levels. Some of the factors which influence the arc-drop are discussed. Methods for representing the effect of arc-drop in fault current calculations are proposed.

Types of Faults

Rectifier faults may be classified on the basis of the nature of the fault, the circuit pattern and action, and the analytical treatment which applies. In order to permit mathematical analysis, certain simplifying assumptions are necessary. These result in a number of idealized cases.

Rectifier faults are of two general types, namely, d-c short circuit and arc-back. Three idealized cases may be defined for each type as illustrated in Figures 1 and 2:

D-C Short Circuit

Case 1—primary impedance only
Case 2—secondary impedance only
Case 3—both primary and secondary impedances

Arc-Back

Case 1—a-c feed only
Case 2—d-c feed only
Case 3—both a-c and d-c feed

D-C Short Circuit

During d-c short circuit, the circuit action is determined by the relative magnitude and location of the various impedances in the rectifier unit and the short-circuit path. Three idealized cases are obtained with equivalent circuits and wave forms as shown in Figure 1. These three cases do not cover all the possible conditions which may be obtained as additional cases may be defined for d-c short circuits with impedance in the fault path and for other rectifier circuits.

CASE 1—D-C SHORT CIRCUIT WITH PRIMARY IMPEDANCE ONLY

In this case, it is assumed that the rectifier transformer d-c windings are perfectly interwound so that all the reactance may be considered to be located in the a-c windings and supply line as shown in Figure 1. The two tubes which are connected to the d-c windings of one phase of the rectifier transformer conduct current alternately so that the fault currents in the a-c winding are the same as in a 3-phase short circuit. Under sustained conditions each tube conducts current for 180 degrees.

STEADY-STATE CONDITIONS

Under sustained conditions, the anode current waves are sinusoidal in form, and each anode carries a half cycle of current whose crest value is

$$i_{as}=\sqrt{2}\,E_s/Z \tag{1}$$

The d-c short-circuit current is equal to the sum of the anode currents, and its average value is

$$I_{ds}=3\times\frac{2}{\pi}\times i_{as} \tag{2}$$

The sustained d-c short circuit current may also be expressed in the form

$$I_{ds}=\frac{2\sqrt{2}}{\pi}\times\frac{VA}{E_s\underline{Z}_c} \tag{3}$$

TRANSIENT CONDITIONS

Under transient conditions, immediately following the start of the short circuit, the fault-current waves in the transformer windings are displaced, and the current in the short circuit exceeds its sustained value. If it is assumed that the anodes are free to conduct at all times and that the fault is a bolted short circuit, the fault currents may be readily determined graphically by a procedure based on a single-phase analysis.

A graphic analysis of the current on d-c short circuit for a 6-phase double-Y rectifier is shown in Figure 3. In this analysis, the current in each pair of anodes is determined as for a single-phase circuit. The short circuit is assumed to occur at the beginning of the positive voltage wave on phase R_1, that is, at switching angle $\beta = 0$. The switching angles on the other two phases differ from this value by their phase displacements of 60 and 120 degrees.

The short-circuit current is obtained by adding the anode current waves which are indicated by the shaded areas. The construction shown is for a decrement

factor $R/X = 0.3$. The maximum value of the fully displaced current wave, which would be attained with zero resistance, is also shown. Its value is twice the crest value of the sustained fault current.

The crest value of the instantaneous current depends upon the switching angle and the circuit reactance as expressed by the R/X ratio. Analyses show that the effect of switching angle is small and may be disregarded as it usually causes less than 5 per cent variation in crest current. However, the transient component due to reactance may cause the maximum instantaneous current to range in value from 1 to 2 times the sustained crest current. The maximum short circuit current may be expressed by the relation

$$i'_{ds}=K_p\frac{\pi}{3}I_{ds} \tag{4}$$

The value of the transient factor K_p for various R/X ratios is given in Figure 5.

Case 2—D-C Short Circuit with Secondary Impedance Only

The 6-phase star circuit shown in Figure 1 represents an idealized case having inductance and resistance that may be lumped in the anode leads. The absence of impedance on the primary side of the transformer permits a determination of the fault current on the basis of six single-phase circuits where the applied voltages have the phase relations determined by the transformer connection. In this case each tube acts independently; and under sustained conditions, the tube conduction period increases toward a value of 360 degrees as the circuit resistance is reduced to zero.

Steady-State Conditions

In contrast to Case 1, with its sinusoidal steady-state currents, the circuit arrangement in Case 2 causes the currents through the impedances to be discontinuous so that the transient is repeated each cycle. Therefore, the crest value of sustained anode current is the same as the maximum instantaneous value for Case 1 as given by

$$i'_{ds}=K_p\frac{\sqrt{2}E_s}{Z_c} \tag{5}$$

The crest value of the short-circuit current is larger than the maximum obtained in the transient state in Case 1 because of the longer conducting interval. The crest short circuit current is given by

$$i'_{ds}=K_s\times 2\frac{\sqrt{2}E_s}{Z_c} \tag{6}$$

Values of K_s may be obtained from Figure 4.

The average value of the short-circuit current may be determined for an idealized case with no resistance by the equation

$$I_{ds}=2\sqrt{2}\frac{VA}{E_sZ_c} \tag{7}$$

It should be noted that this value is π times the value obtained for Case 1 as given by equation 3.

When resistance is present the sustained short circuit current will have a lower value. This is shown in Figure 5.

Transient Conditions

Conduction During First Cycle. If the short circuit occurs at the instant the voltage on phase 1 is going through zero, conduction takes place initially in phases 5, 6, and 1. Sixty degrees later phase 2 starts conducting, and the remaining phases enter in sequence.

Neglecting resistance the currents in phase 1 and all succeeding phases are fully displaced. However, the short-circuit current does not reach its maximum value until phase 6 starts conducting a second time and steady-state conditions are reached.

Figure 2. Arc-back—idealized conditions

Figure 1 shows a sketch of the short-circuit current and the current in phase 1 that would exist in this case with a small R/X ratio.

Effect of Interphase Transformer. Neglecting the interphase transformer and treating the 6-phase star circuit yields results which apply with sufficient accuracy to the 6-phase double-Y circuit. Introducing the interphase transformer causes no change in the short-circuit current. Some redistribution of current among the anodes is caused, but the maximum change is less than 2.0 per cent of the crest value of anode current.

Case 3—D-C Short Circuit with Both Primary and Secondary Impedance

This is the general case which is usually encountered in practice. Its circuit action combines the effects obtained in the first two cases. With reactance and resistance in both primary and secondary windings of the rectifier transformer, the crest value of the anode current is still represented by the displacement factor K_p. X and R in this case are the sum of the components in the primary and secondary windings.

The short-circuit current has a peak value which falls between the two extremes represented by K_p and K_s in Figure 4. The exact value has not been determined, but it is dependent upon the ratios R_p/R_s, X_p/X_s and the total resistance to total reactance ratio R/X. The trend may be expressed as follows: For a given X_p/X_s ratio, the value falls upon the upper curve when the R/X ratio is equal to zero, but approaches rapidly the lower curve as the R/X ratio increases.

The ratios X_p/X_s and R_s/R_p determine the rapidity with which the value approaches the lower curve. The larger these ratios, the more rapidly the value approaches the lower curve.

For practical ratios of these quantities where no reactance is intentionally added in the anode leads, the lower curve applies for usual R/X ratios.

Arc-Back

During arc-back, the circuit action is determined primarily by the sources of voltage producing the fault current. Three idealized cases may be defined with equivalent circuits and wave forms as shown in Figure 2.

Case 1—Arc-Back with A-C Feed Only

In this case, the current flow in the faulty anode is established by the a-c supply and it is assumed that there is no other source of voltage. The equivalent circuit is shown in Figure 2. A 3-phase rectifier is assumed as it represents one commutating group of the rectifier. During arc-back, a reverse current flows in the faulty anode which is equal to the sum of the forward currents in the two normal anodes.

In the treatment presented in the original paper,[1] this case was referred to as arc-back in a wye and sustained values of current were given. Further studies indicate that the first cycle values are generally more important than sustained values in system studies.[5]

The first cycle crest values of the reverse current in the faulty anode and the forward current in the normal anodes may be determined by equations 8 and 9.

Crest reverse current in faulty anode is

$$i'_{ar} = K_r \frac{\sqrt{2}E_s}{Z_c} \qquad (8)$$

Crest forward current in normal anodes is

$$i'_{af} = K_f \frac{\sqrt{2}E_s}{Z_c} \qquad (9)$$

Values of the reverse current and forward current factors as a function of the R/X ratio are given in Figure 6. These factors give the crest value of current obtained during the first cycle when arc-back occurs at the end of conduction. It is assumed that the arc-drop is represented as an equivalent resistance in determining the R/X ratio.

Case 2—Arc-Back with D-C Feed Only

This is an idealized case where all the current in the faulty anode flows in the d-c system. The equivalent circuit is a single loop containing an alternating and a direct voltage in series. The current consists of an alternating component of constant magnitude and a direct component which increases exponentially with

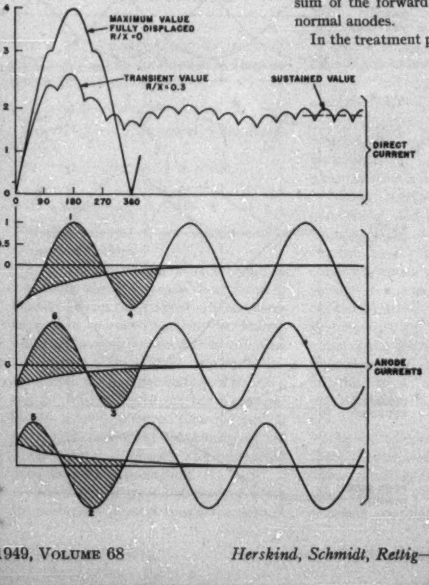

Figure 3 (left). Graphic analysis of transient current on d-c short circuit with primary impedance only

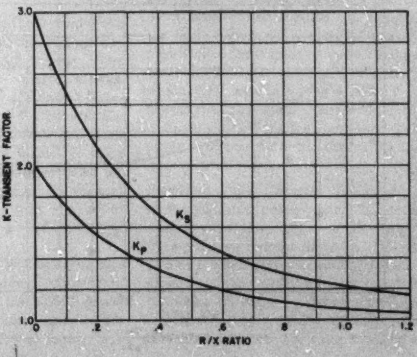
Figure 4 (below). Transient factors for determining crest values of anode current and d-c short-circuit current



time until it is limited by resistance. Such a condition may be realized in practice if all the normal anodes of the rectifier are prevented from firing at the time of fault or may be approximated if a number of rectifiers are paralleled on the same d-c bus.

The reverse current in the faulty anode is given by the equation

$$i_{dr}=\frac{E_d'}{R_3}\left[1-\epsilon^{-\frac{R_d}{L_d}(t-t_1)}\right]+\frac{\sqrt{2}E_s}{Z_3}\times$$
$$\left[\sin(\omega t-\theta_3)-\epsilon^{-\frac{R_d}{L_d}(t-t_1)}\sin(\omega t_1-\theta_3)\right] \quad (10)$$

The idealized conditions are not closely approximated in practice and useful results of adequate accuracy may be obtained by an approximate expression based on the following assumptions: First, it is assumed that the arc-back occurs at the zero point of the a-c voltage wave when $t_1=0$. This is justified on the basis that the majority of arc-backs occur at the end of conduction which is usually within a few degrees of the zero point of the voltage wave. Second, it is assumed that the resistance of the fault path is low in comparison with the inductance so that $\theta=90$. The approximate value of the reverse current is given by the simplified equation

$$i_{dr}=\left[\frac{E_d'}{R_3}-\frac{\sqrt{2}E_s}{Z_3}\right]\left[1-\epsilon^{-\frac{R_3}{L_3}t}\right]+$$
$$\frac{\sqrt{2}E_s}{Z_3}[1-\cos\omega t] \quad (11)$$

CASE 3—ARC-BACK WITH BOTH A-C AND D-C FEED

This is the case usually encountered in practice and combines the action of the first two cases. In order to simplify the analysis, the action is considered on the basis of a single wye. During arc-back, the current in the faulty anode is a combination of a-c feed from the two normal anodes of the wye and d-c feed from a single d-c source representing all other anodes and parallel sources.

Currents feeding into an arc-back from a counter electromotive force load and from the normal anodes in a faulted wye are additive components of the current in the faulted phase. Each of these components is smaller than the value obtained in either Case 1 or Case 2, but their sum yields an arc-back current larger than either component considered separately. A method is described in the following analysis for obtaining the exact theoretical values of currents in the faulty anode, the normal anodes, and the d-c feed.

Circuit Analysis. The equivalent circuit for this case is shown in Figure 2. Paralleled converting equipment, counter electromotive force load, and the normal wye of the 6-phase double-Y rectifier are reduced to an equivalent voltage source E_d', resistance R_d, and inductance L_d. The action of individual phases is considered only in the faulted wye. The phases in this wye are designated in their normal conducting sequence. R_1 is the faulty phase and R_2 and R_3 are the normal phases in the faulted wye. L_c and R_c are the commutating inductance and resistance per phase. Arc-drop is treated as an equivalent resistance whose value is included in R_c.

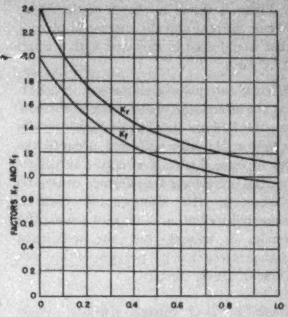


Figure 6. Factors for determining reverse and forward current during arc-back with a-c feed only

Circuit action during the first cycle following a commutation arc-back is shown in Figure 7. For purposes of defining circuit action, the cycle of operation is divided into four intervals. The divisions correspond to the instants at which a phase either starts or stops conducting. The current in phase 1 and the feed-back

Figure 10 (right). Power circuit during fault tests on 6-anode 200-kw 300-volt rectifier

current are continuous, and the intervals are determined by conduction in the two normal phases as follows:

Interval 1—conduction in phase 2.

Interval 2—conduction in both phases 2 and 3.

Interval 3—conduction in phase 3.

Interval 4—conduction in neither normal phase.

During interval 1, the circuit action proceeds as follows:

A current will start flowing from anode 2 to anode 1 with values as determined in Case 1. Upon this current will be superimposed a current from the d-c source, whose value is determined from equation 1. The a-c voltage which applies in this equation is the average voltage of phases 1 and 2. The current from the d-c source divides equally between phases 1 and 2, one-half its numerical value being added to the current in phase 1 and subtracted from the current in phase 2.

The end of interval 1 is reached when the voltage of phase 3 equals the voltage at the terminals of the rectifier as given by

$$e_d = E_d' - R_d i_{dr} - L_d \frac{di_{dr}}{dt} \tag{12}$$

where i_{dr} is the feed-back current during interval 1. A later time may apply if phase control is used.

During interval 2, all three anodes are conducting, and the net a-c voltage appearing in the d-c circuit is zero. The current from the d-c source divides equally between anodes 1, 2, and 3, one-third of its numerical value adding to the current in anode 1 and subtracting from the currents in anodes 2 and 3. The value of the d-c current is determined for the series circuit including E_d', L_d, R_d, and one-third of L_c and R_c with the initial value as determined at the end of interval 1.

The a-c components of current in the three transformer phases follow the values resulting from a complete 3-phase short circuit. The transient components maintain continuity between intervals 1 and 2 and decay with the exponential $(R_c/L_c)t$.

Interval 2 ends when the current in phase 2 reaches zero. Calculation of the currents in anodes 1 and 3 and in the d-c source at this time determines the initial conditions for interval 3.

The action in interval 3 is similar to that in interval 1 in that there are two conducting anodes. The average voltage of anodes 1 and 3 during this interval is opposed to the voltage of the d-c source and usually reverses the rate of rise of cathode current.

The transition from interval 3 to interval 4 is determined when the current in phase 3 goes to zero. The same current is then carried by the faulty anode and the d-c source during interval 4. Because the a-c voltage on phase 1 is opposed to the d-c voltage during most of this interval, the fault current is decreased. Interval 4 ends when the voltage of phase 2 exceeds the voltage at the rectifier terminals, at which time intervals 1 to 4 will be repeated with new initial conditions.

Appendix II gives the equations which apply to this circuit action during the four intervals.

Sustained Fault Current. The value of sustained fault current may be determined by carrying out the circuit analysis for a sufficient number of cycles. It may also be found by trial, assuming values of i_{dr} and t at the start of interval 1 and determining the resulting currents throughout the sequence. At $\omega t = 360$ degrees the current should have the value assumed at

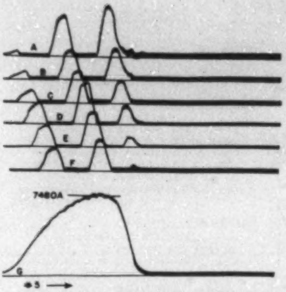

Figure 11. (Test 5) Fault current during d-c short circuit (inductance in the short), 6-anode 200-kw 300-volt rectifier

"A" to "F" inclusive—anode currents
"G" —cathode current

the start of interval 1, and anode 2 should be ready to start conducting.

Factors Modifying Circuit Action. The foregoing analysis describes a commutation arc-back in a free rectifier with three anodes. A number of factors may influence the circuit action, particularly the initial action.

Phase of Arc-Back—While arc-back commonly occurs at the end of commutation, it may occur at a later time during interval 1 or during intervals 2 or 3. The initial peak of reverse current is reduced in such cases. (Compare tests 43 and 45, Figures 17 and 18.)

Interphase Transformer—The interphase transformer acts as a large inductance to reverse current from the d-c load until saturation occurs. At the time of a commutation arc-back, the interphase transformer flux may have reached 0.1 to 0.5 times its saturation value, depending upon the design of the interphase transformer and the amount of phase control used.

Phase Control—Phase control may delay the entry of a normal anode and thereby reduce its contribution to the arc-back.

Approximate Solution. While the foregoing analysis for the case of arc-back with a-c and d-c feed constitutes an exact method of procedure, its use is likely to prove cumbersome and approximations of reasonable accuracy are well worth consideration.

The simplest approximation consists of determining upper limits for fault current values. Thus the current in the normal anodes cannot exceed the value for arc-back in a wye and the current in the d-c source generally cannot exceed the value for d-c feed only. The current in the faulty anode cannot exceed the sum of these values.

A more precise approximation results by assuming that on the average two anodes are conducting throughout the cycle and that the resulting impedance to d-c feed includes one-half the transformer impedance. A further assumption is that the net a-c voltage in the d-c feed circuit is one-half of E_s. This permits calculation of the d-c feed as described in Case 2. Since two anodes are assumed to be conducting, half this value is added to the current in the faulty anode resulting from arc-back in a wye and is subtracted from the current in the normal anodes.

Arc-Drop

There may be considerable variation in the arc-drop voltage across a rectifier on successive trials at the same fault current value. Tests 30 and 31 (Figure 16) show the arc-drop voltage in a pumped ignitron at pulse currents of approximately 25,000 amperes crest. In test 30, the arc-drop voltage wave has a rounded crest at 87 volts. Test 31 shows a sudden rise in voltage from 70 to 152 volts near the crest of the wave approximately doubling its value. In many cases, the crest value of the arc-drop voltage does not have particular significance insofar as its influence on the magnitude of fault current is concerned, since the break in the arc-drop voltage wave does not occur until the fault current has reached its crest value. Average values of the arc-drop voltage would appear to be more representative of the effect of arc-drop as they are a measure of both the volt-seconds appearing across the tube and the energy dissipated in the arc during the fault. Average values do not give undue weighting to high arc-drop voltages of short duration.

"D"—anode-to-cathode voltage in faulty tube

Arc-drop measurements on a sealed ignitron during pulse-current tests are shown by test 23 (Figure 15). This test shows a triangular arc-drop voltage wave form starting from a high value at the beginning of the conduction period and dropping regularly to approximately zero at its end. Again in this case the initial value of the arc-drop would not appear to be as significant as its average value in determining the current obtained during faults.

The nature of the arc phenomena at fault current levels is not accurately known. In the case of the pumped ignitron, the sharp rise in voltage would appear to be the result of arc starvation. Observations show that this voltage occurs at a quite definite current level. When fault currents in excess of this critical value flow through the tube, the rise in voltage occurs before the current crest, causing a considerable increase in the averaged value of arc-drop voltage for a small increase in fault current. In the case of the sealed ignitron, observations show that when the tube is passing currents of fault magnitude, a considerable part of the cathode current is collected on the walls of the tube. The shorter arc-path which results may account for the reduction in arc-drop in the latter part of the conducting period.

Average arc-drop values for a sealed ignitron rectifier tube of the type used in units ranging in size from 200 to 500 kw for 250- and 600-volt applications are shown in Figure 8. Typical arc-drops for a pumped ignitron of the type used in units ranging in size from 1,000 to 2,500 kw for 250- and 600-volt applications are shown in Figure 9.

Two dashed lines representing equivalent resistance are shown in each figure. The lower value of resistance in each figure would be applicable to an equivalent circuit containing a battery and resistance.

The higher value of equivalent resistance is an approximation accounting for the total arc-drop. This approximation simplifies analytical treatment and is of commensurate accuracy with the determination of other circuit parameters.

Calculated and Test Results

Extensive fault-current tests were made on a 6-phase 200-kw 300-volt sealed ignitron rectifier. The complete circuit of the rectifier unit and the associated a-c supply and d-c load systems during these tests, together with the circuit constants, are shown in Figure 10. Oscillographic records of fault currents are shown by six tests included in the illustrations.

The fault current calculations are as follows:

D-C SHORT CIRCUIT

The total impedance of the circuit is determined as follows:

Rectifier Transformer

$\underline{Z}=0.0597$ (on 230-kva base)

$$\underline{R}=\frac{P_r}{VA}=\frac{3{,}707+346}{230\times 1{,}000}=0.0176$$

$$\underline{X}=\sqrt{\underline{Z}^2-\underline{R}^2}=0.0570=\underline{X}_p+{}^1/_2\underline{X}_s$$

Rectifier Tubes

$\underline{R}=0.0015/1.042=0.00144$

Using other values as given in Figure 10.

Total $\underline{X}_c=0.0250+0.0575=0.0825$
Total $\underline{R}_c=0.0031+0.0176+0.00288+0.00144=0.0250$
Total $\underline{Z}_c=0.0860$

Sustained Direct Current

$$I_{ds}=0.9\times\frac{VA}{E_s\underline{Z}_c}=0.9\times\frac{230{,}000}{283\times 0.0860}$$
$$=8{,}500 \text{ ampere (average value)} \quad (3)$$

Ratio $R/X=0.0250/0.0825=0.304$
$K_p=1.41$ (Figure 4)

Transient Direct Current

$$i_{ds}'=1.41\times\frac{\pi}{3}\times I_{ds}=12{,}500 \text{ amperes (crest value)} \quad (4)$$

ARC-BACK WITH A-C FEED ONLY

The ohmic value of commutating impedance is calculated from the total per unit value as determined for the case of d-c short circuit.

$$Z_c=\frac{3E_s^2}{VA}\,\underline{Z}_c=1.042\times 0.0860=0.0895 \text{ ohm}$$

Using the R/X ratio determined for d-c short circuit

$K_r=1.57$, $K_f=1.35$, (Figure 5)

Crest Reverse Current

$$i_{ar}'=K_r\frac{\sqrt{2}E_s}{Z_c}=1.57\times\frac{\sqrt{2}\times 283}{0.0895}=7{,}020 \text{ amperes} \quad (8)$$

Crest Forward Current

$$i_{af}'=K_f\frac{\sqrt{2}E_s}{Zc}=6{,}040 \text{ amperes} \quad (9)$$

ARC-BACK WITH D-C FEED ONLY

In calculating the fault current in this case, the total ohmic resistance of the d-c fault path is determined by adding the resistances of the various elements.

	Ohms
Supply line 0.0031×1.042=	0.00324
Rectifier transformer (3,707/230×1,000)1.042=	0.0168
Interphase transformer=	0.0016
Anode cable=	0.003
D-c cable=	0.0034
D-c motor=	0.0170
Total R_3=	0.0450

The tube arc-drop is not included as the

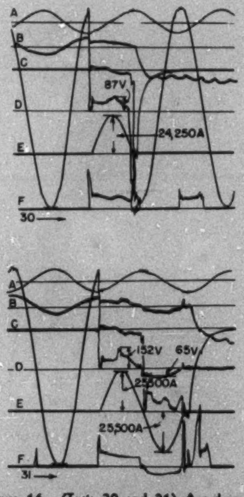

Figure 16. (Tests 30 and 31) Arc-drop on pumped ignitron during current pulse

"A"—60-cycle timing wave
"B"—grid-to-cathode voltage
"C"—grid current
"D"—anode-to-cathode voltage (arc-drop)
"E"—anode current
"F"—ignitor-to-cathode voltage

car-back was simulated by a switch.

The total inductance in the fault path is determined from the reactances of the various elements.

	Henrys
Supply line $0.025\times1.042/377=$	69.1×10^{-6}
Rectifier transformer $0.0575\times1.042/377=$	159.0
Interphase transformer =	15.8
D-c cables =	79.5
D-c motor =	46.0
Total $L_3=$	369.4×10^{-6}

The total reactance and impedance are

$X_3=\omega L_3=377\times369.4\times10^{-6}=0.139$ ohm

$Z_3=\sqrt{X_3^2+R_3^2}=0.146$ ohm

The ratio $R_3/X_3=0.324$.

The approximate value of the current in the faulty anode is given by the equation

$$i_{dr}=\left[\frac{E_d'}{R_3}-\frac{\sqrt{2}E_s}{Z_3}\right]\left[1-\epsilon^{\frac{-R_3}{X_3}\omega t}\right]+\frac{\sqrt{2}E_s}{Z_3}\left[1-\cos\omega t\right] \quad (11)$$

Substituting

$$\frac{E_d'}{R_3}=\frac{280}{0.045}=6{,}230 \text{ amperes}$$

$$\frac{\sqrt{2}E_s}{Z_3}=\frac{\sqrt{2}\times283}{0.146}=2{,}740 \text{ amperes}$$

at $\omega t=\pi$, $1-\epsilon^{-0.324\omega t}=0.632$, and $(1-\cos\omega t)=2$

$\omega t=3\pi$, $1-\epsilon^{-0.324\omega t}=0.950$, and $(1-\cos\omega t)=2$

$\omega t=5\pi$, $1-\epsilon^{-0.324\omega t}=0.995$, and $(1-\cos\omega t)=2$

The approximate currents in the faulty anode at the end of the first, third, and fifth half cycles are 7,680, 8,790, and 8,960 amperes, respectively.

ARC-BACK WITH BOTH A-C AND D-C FEED

If we assume that on the average, two phases are conducting and that the average a-c voltage in the circuit is one-half E_s, then

Total $L_1=255.4\times10^{-6}$ henries

$X_1=\omega L_1=0.096$ ohm

$R_1=0.0335$ ohm

$R_1/X_1=0.348$ ohm

$Z_1=0.101$ ohm

From equation 11

$$\frac{E_d}{R_1}=\frac{280}{0.0335}=8{,}400 \text{ amperes}$$

$$\frac{\sqrt{2}E_s}{Z_1}=\frac{\sqrt{2}\times283}{2\times0.101}=1{,}980 \text{ amperes}$$

The approximate currents in the d-c source at the end of the first, third, and fifth half cycles are respectively 7,280, 9,960, and 10,340 amperes.

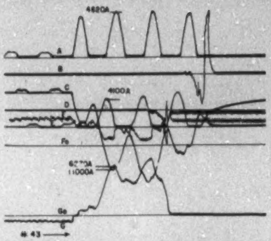

Figure 17. (Test 43) Fault current during arc-back with both a-c and d-c feed (arc-back approximately 120 degrees after end of conduction) 6-anode 200-kw 300-volt rectifier

"A"—anode number 1 current

"B"—a-c circuit breaker volts pole number 2

"C"—anode number 2 current (faulty anode)

"D"—d-c circuit breaker volts

"E"—anode number 3 current

"F"—d-c voltage

"G"—cathode current

The approximate current in the faulty anode is obtained by adding half these values to the value derived from Case 1. This results in an ultimate peak value of 7,020+10,380/2=12,210 amperes.

COMPARISON OF TEST AND CALCULATED VALUES

Test 9 (Figure 12) shows the fault currents during d-c short circuit with a bolted short. Calculated and test values are as follows:

	Calculated, Amperes	Test, Amperes
Average sustained current	8,500	7,700
Crest transient current	12,500	11,000

Test 5 (Figure 11) shows the fault current during d-c short circuit with inductance in the short. The average sustained current is 7,480 ampères and is only slightly below that obtained on test 9 (Figure 12).

Test 29 (Figure 13) shows the fault current during arc-back with a-c feed only with the rectifier operating on only three tubes. Calculated and test values are as follows:

	Calculated, Amperes	Test, Amperes
Crest reverse current	7,020	7,440
Crest forward current	6,040	6,370

A switch was used to short the faulty tube in making the arc-back test. Normal arc-drop was assumed in making the calculations, giving a calculated value which is too low.

Test 32 (Figure 14) shows the fault current during arc-back in a double wye circuit with no external d-c load. This record shows the effect of the current contribution of the anodes of the normal wye.

Test 45 (Figure 18) shows the fault current during arc-back with both a-c and d-c feed when the arc-back occurs at the end of conduction. Calculated and test values are as follows:

	Calculated, Amperes	Test, Amperes
Reverse current in faulty anode,		
At end of 1st half cycle	10,660	8,680
At end of 3rd half cycle	12,000	12,300
At end of 5th half cycle	12,200	12,900
Maximum d-c feed back	6,230	7,030

The effect of the time taken for saturation of the interphase transformer was not considered in the calculation. This results in too high a calculated value for the first half cycle.

Summary

A comprehensive procedure for the analysis of fault currents in power rectifiers has been developed and some of the more usual cases have been analyzed for the 6-phase double-Y circuit. However, further analyses are still required to cover all the conditions which may be encountered in practice and provide a ready means for determining fault currents.

Appendix I. Symbols

i=instantaneous current, also crest value of sinusoidal component of current

i'=crest value of instantaneous current including transient component

I=average value of current

First subscript:

a—anode (phase) current

d—d-c bus current

1, 2, 3—phase 1, 2, 3

Second subscript:

s—d-c short circuit

f—forward (normal) direction of flow

r—reverse direction of flow

1, 2, and so forth—start of intervals 1 and 2

e=instantaneous voltage

E_s=open-circuit, secondary voltage of rectifier transformer in rms volts

E_d'=counter electromotive-force component of d-c load voltage

L_c, R_c, $Z_c=\sqrt{R_c^2+X_c^2}$—line-to-neutral commutating inductance, resistance and impedance of rectifier

L_d, R_d=inductance and resistance of d-c circuit elements external to rectifier

L_p, R_p=inductance and resistance on primary side of rectifier

$R_s L_s$ = inductance and resistance on secondary side of rectifier transformer

Note

$L_p + L_s = L_c$

L_1, R_1, $Z_1 L_1 = L_d + {}^1/_2 L_c$, $R_1 = R_d + {}^1/_2 R_c$,
$Z_1 = \sqrt{R_1^2 + \omega^2 L_1^2}$

L_2, $R_2 L_2 = L_d + {}^1/_3 L_c$, $R_2 = R_d + {}^1/_3 R_c$

L_3, R_3, $Z_3 L_3 = L_d + L_c$, $R_3 = R_d + R_c$,
$Z_3 = \sqrt{R_3^2 + \omega^2 L_3^2}$

t_1, t_2, and so forth = time at beginning of intervals 1 and 2

Phase 2 voltage zero is the time reference for defining circuit action during arc-back with a-c and d-c feed.

β = switching angle (angle after voltage zero at which fault occurs).

$$\theta = \tan^{-1}\frac{\omega L}{R}$$

Discussion

A. J. Maslin: (Westinghouse Electric Corporation, Sharon, Pa.): The treatment of short circuits and arc-backs presented in the paper by Herskind, Schmidt, and Rettig is an interesting addition to the published information on these subjects. In particular, the approximate solution for arc-back with a-c and d-c feed is most welcome, for it permits an estimate of the fault currents for this most important case, without laborious point-by-point computation of the current values in individual branches of the circuit. Everyone concerned with the design, application, or use of rectifier equipment will wholeheartedly endorse the authors' statement: "A complete treatment of the fault currents obtained in the widely used 6-phase double-Y circuit is particularly desired."

Generally, short circuits are relatively rare in comparison with arc-backs, and result in lower maximum fault currents in individual rectifying devices and transformer windings. As explained in the paper, all actual installation will have the a-c circuit impedance divided between the a-c winding and the d-c winding circuits. Because of the characteristics of rectifier transformers, the ratio X_p/X_s will usually be of the order of ten or more, hence the assumption that all impedance is located in the a-c winding circuit is usually completely justified. Short-circuit currents determined on this basis will be in error by being slightly too small.

Other factors, mentioned but briefly in the paper, are the inductance and resistance which are always present in the d-c circuit. Both of these operate to reduce the short-circuit current, usually to an extent more than sufficient to offset the error introduced by assuming all a-c circuit impedance located on the a-c winding side of the transformer. In the extreme case where the d-c circuit inductance is sufficient to completely smooth the direct current, the anode currents, instead of being sinusoidal with a crest value given by equation 1 of the paper, are approximately trapezoidal with a crest value only 87 per cent as great.

For most double-way circuits the location of the a-c circuit impedance is of no consequence. The short-circuit current is the same whether the impedance is all on the

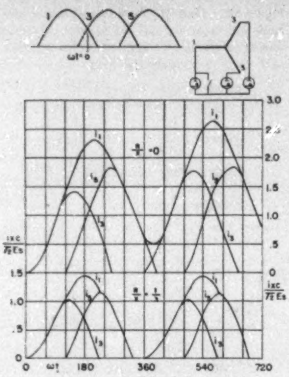

Figure 1. Arc-back, a-c feed only

a-c winding side, all on the d-c winding side, or divided between them.[1]

In spite of the great progress made in reducing the frequency of occurrence of arc-backs, they remain the most common rectifier fault. They are also the most severe, and are best isolated by high-speed anode-circuit switchgear. Because of this, experimental and analytical determinations of arc-back currents continue to receive a great deal of attention.

One of the simpler analytical treatments covers arc-back in a wye with a-c feed only, as presented in the paper. The values of K_r and K_f given in Figure 6 of the paper, however, appear to be rather high. Figure 1 of this discussion was calculated from equations which assume the arc to be equivalent to a resistance, and permit consideration of time of occurrence of the fault and amount of phase control. It applies to an arc-back occurring at no load, at the time $\omega t=0$, for a controlled rectifier operating with zero retard. The values of K_r and K_f from Figure 6 of the paper and Figure 1 of this discussion, as well as values of K_r taken from Figure 2 of a paper by H. Forssell,[2] are compared in Table I. It should be noted that Forssell's Figure 2 applies to arc-back in a wye with a-c feed only, at no load, and for an uncontrolled rectifier.

The arc-back is initiated at the instant two anodes have the same potential ($\omega t=0$ in Figure 1 of this discussion) and the third anode begins to carry current at the instant its potential becomes positive ($\omega t=90$ degrees in Figure 1 of this discussion). The data cited are for the assumption that the arc is equivalent to a resistance ($\alpha=0$ in Forssell's Figure 2). An explanation of the basis of the values in Figure 6 of the paper would be appreciated.

The use of a direct voltage in series with inductance and resistance to simulate the action of the load, and of the second wye of the 6-phase double-Y circuit, is a very useful artifice.

It was suggested but not developed in a previous paper.[3] A discussion,[4] however, presented a detailed comparison of test values of arc-back current in a double-Y circuit with calculated values for a single wye with both a-c and d-c feed. The equations used in this comparison permit taking account of the load being carried, the time of occurrence of arc-back, and the amount of phase control. These calculations, while they yield highly satisfactory results, are very laborious to make. The approximate solution demonstrated in the paper is therefore most welcome.

Whenever arc-back currents are calculated by these methods, the influence of switchgear must be given careful consideration. With high-speed switchgear, either cathode or anode, the crest calculated current will not be realized because the opening switch will introduce an important voltage drop into the d-c feed circuit, or the anode circuit itself, early enough to effect some degree of current limitation. A number of arc-back tests[5] on 600-volt 6-phase double-Y rectifiers, feeding regenerative loads through high-speed cathode circuit breakers, indicate that the first crest of arc-back current is about 90 per cent of that calculated on the basis of both a-c and d-c feed; while the second and subsequent crests are about 15 per cent greater than calculated on the basis of a-c feed only, this increase being due to the contribution of the other wye.

C. C. Herskind, A. Schmidt, Jr., and C. C. Rettig: In his discussion, Maslin has compared values of K_r and K_f in Figure 6 of the paper with values calculated by himself and also by Forssell in another paper. The differences noted by Maslin may be explained as follows:

1. We have assumed a free rectifier, with conduction beginning as soon as the anode becomes positive. The per unit base for K_r and K_f is $\sqrt{2}E_s/Z$.

2. Maslin has assumed phase control which prevents conduction from starting for 30 degrees after the anode becomes positive with respect to the transformer neutral. While such phase control does not affect normal operation of the rectifier, it does serve to reduce the a-c feed during arc-back.

3. Forssell uses a base of $\sqrt{2}E_s/X$ instead of $\sqrt{2}Es/Z$. When this change in base is made, Forssell's curve agrees closely with ours. There is a slight difference at $R/X=0$, in the plotted curves. The calculated value of K_r at this point is 2.366.

The treatment of fault currents is by no means complete. Among the cases that merit consideration are:

1. Contribution of normal wye in arc back of double-Y rectifier.
2. Effect of impedance in d-c fault.
3. Circuits other than double-Y.

Die-Cast Rotors for Induction Motors

L. C. PACKER
MEMBER AIEE

Synopsis: There are many problems to solve in connection with the manufacture of die-cast rotors that require the co-ordinated efforts of the design and manufacturing engineers. Forcing molten aluminum under high pressures into the rotor slots causes excessive stray load losses unless the laminations are insulated properly and strain relieved, and the slots insulated from the cast aluminum conductors. Heating processes may be necessary after machining the surface. It is also necessary to select the best and most economical die casting methods, equipment, and furnaces. The moulds properly gated, holding pressure, pressure on the die-casting metal, and temperature are all important to the production of homogeneous die cast rotors free from impurities. With proper control, die-cast rotors can be manufactured to relatively close limits of rotor resistance and with the stray load losses reduced to a satisfactory value resulting in satisfactory performance, and generally at a lower cost than copper cage rotors. This paper explains the cause of the stray load losses, processing to reduce them, and suitable test methods. There are curves showing the effect of excessive stray load losses upon performance, results of various processes, and illustrations of die-casting methods and diagrams of equipment for testing die-cast rotors.

DIE-CAST rotors for ratings through 125 horsepower now are being produced in addition to those which have been manufactured for about 25 years in sizes ranging from about 1/200 to 50 horsepower in quantity production. They have many advantages to both the ultimate user and the manufacturer. The die cast rotor is a solid and fairly homogeneous mass that retains its balance, and in general gives the customer good all-around performance. The manufacturer can generally make die cast rotors at a lower cost than copper cage rotors, which is to the advantage of both the customer and manufacturer. Since World War II, aluminum, which is used in die-cast rotors, has been more plentiful and lower in cost than copper. The shortage of copper made it very difficult for manufacturers of copper cage rotors.

There are many pitfalls that must be guarded against in the successful manufacture of die-cast rotors. They are not just ordinary die castings and cannot be treated as such. Excessive stray load losses, porosity, and broken bars can be very detrimental to the performance, cause high factory rejects and trouble in operation. Some of these stray losses also can exist in copper cage rotors but to a much smaller degree. Therefore, before starting to lay out the design and manufacturing methods for die-cast rotors, it is advisable, first, to study the applications for which the motor is intended, and then the source of the losses in induction motors. Next to consider are the results of forcing pure aluminum or aluminum alloy into the rotor slots and making contact with the wall of the slots. If there is insulation on the laminations, there may still be exposed iron surfaces in the slots. If the source of the various losses, their effect upon the performance of the motor and the methods for reducing or eliminating them are known, then plans can be made to proceed with the details of design and processing methods.

A dependable method of testing die cast rotors is essential to control the quality.

There are die-casting problems, also, that must be worked out, and a study of equipment, gating, temperatures, and pressures must be made. Some of these problems can be worked out in pilot runs after the equipment is set up.

The main purpose is to point out the problems and give examples of experiences that lead up to production, and problems in manufacturing that affect the performance of the motor. Experience has proved that solving these problems makes it easier and less costly to get production up quickly and maintain the quality of the product.

This paper was prepared around data pertaining to fractional horsepower motors, but it may also apply to larger single-phase motors. The extent of the various losses and effects upon larger polyphase motors depends upon the design.

The source of most of the troubles, which will be discussed first, applies to both single-phase and polyphase motors.

Source of Losses in Induction Motors

In a copper cage rotor, the conductor may contact the walls of the rotor slots at various points if the conductor is buckled during the riveting process and due to skewing, but the points of contact are relatively few in the slot compared to the surface contact of the conductors in a die cast rotor.

In a die-cast rotor, hot aluminum is forced into the slots under pressure. It can short circuit all of the laminations, which in turn short circuit the conductors in part or throughout the slots, thereby causing a net-work of many circuits for circulating currents.

Losses in the ordinary squirrel-cage motor, not including the ordinary losses due to normal current in both windings, bearing friction, windage, and losses in the end bells, are those due to the fundamental frequency, tooth pulsation frequency, surface losses, losses due to spreading of the main flux back of the teeth, harmonics other than slot harmonics, and those caused by the eddy current in the rotor cage winding.

The stray load losses over and above

Paper 49-69, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted July 15, 1948; made available for printing December 28, 1948.

L. C. PACKER is manager of motor engineering, Westinghouse Electric Corporation, Springfield, Mass.

The author wishes to acknowledge the assistance of G. E. Monchamp, an associate, for his assistance in the development of the reverse rotation method of testing die-cast rotors and calculation of losses as used in this paper.

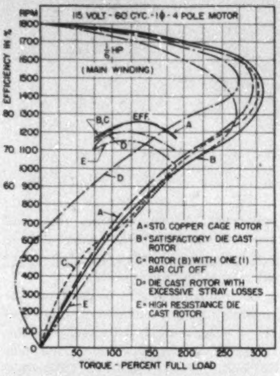

Figure 1. Speed-torque and efficiency on the main winding with typical cases of satisfactory and defective die-cast rotors and copper-cage rotors of single-phase motors

the normal inherent losses in a given design may be caused by bending of the laminations, punching strains, excessive pressure between laminations, poor interlamination insulation and burrs, plus the short circuiting effect in the slots of die-cast rotors.

Bending of the laminations and punching strains decreases the permeability of the steel and increases the magnetic densities, magnetizing current, and hysteresis iron loss. In single-phase motors the magnetizing current is relatively large. Any increase will increase the copper losses more than in polyphase motors. There also are harmonics due to hysteresis, the magnitude depending upon the saturation.

Burrs, insufficient interlamination resistance, and excessive pressure between laminations result in eddy current losses.

The tooth pulsation frequency losses have two causes:

1. High-frequency flux pulsations penetrating a short distance into the core.
2. High-frequency flux which extends throughout the whole magnetic circuit due to pulsation or reluctance as the teeth pass opposing teeth.

The high-frequency flux pulsations in the teeth also cause hysteresis and eddy current losses in the teeth.

The high-frequency circulating current in the cage winding of the rotor may damp out the high-frequency flux pulsations in the rotor teeth. However, it may cause the pulsations to be reflected to the stator teeth and produce large pulsation losses in the stator teeth. While the rotor tooth frequency may be partially damped, the high-frequency circulating currents in the cage winding may cause a high effective resistance due to the skin effect, thus increasing the losses.

Saturation of the teeth where tooth pulsations are present causes high-frequency leakage flux, both tangential and radial in the slots. This causes high eddy current losses in the conductors of the cage winding in the rotor. Therefore, there is a very rapid increase in the pulsation losses with increase in induction of the iron. There have, however, been instances indicating that, with higher fundamental flux density, the stray load loss is less for the same ampere turn value.

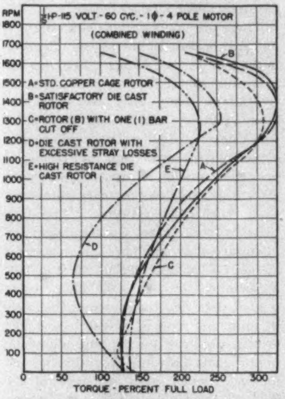

Figure 2. Speed-torque curves with the combined winding with typical cases of satisfactory and defective die-cast rotors and copper-cage rotors of single-phase motors

Same rotors as Figure 1

In fractional horsepower motors, punching strains penetrate farther into the teeth (compared with tooth width) than is the case in the larger industrial or power machines. Because of this, there is greater saturation in the small machines due to the decreased permeability and also high hysteresis losses.

Finishing the surface of the rotor core by machining, drives the tooth tips into the die-cast conductor. This increases the eddy current losses and short circuits the conductors within the slots. The bridges of a closed slot rotor also are driven into the die-cast conductor. In either case, the tooth tips or bridges are strained and thus saturated more than normal.

The Effect of Excessive Stray Load Losses and Rotor Resistance upon Performance

Stray load losses cause a reduction in efficiency, pull-up and breakdown torques. The effect is generally greater in single-phase motors than in polyphase motors. The starting torque is seldom reduced. If there is any change at all, it is a slight increase in starting torque. Apparently this is because the excessive iron loss has the effect of increasing the rotor resistance which increases the starting torque.

Probably the greatest effect of excessive stray losses is upon the pull-up torque. In some applications, this torque may be reduced so much that the motor cannot get the load up to speed. This is especially true with compressor applications.

The results of excessive rotor resistance are well known. The efficiency and breakdown torque are reduced and the starting torque and slip are increased.

Figures 1, 2 and 3 show typical cases of performance of die cast as well as copper cage rotors for a given design. Curve *A* is for standard copper cage rotors, curve *B* is for a satisfactory die-cast rotor, curve *C* is for rotor *B* with one broken bar, and curve *D* is a typical case of rotors with excessive stray load losses.

Figure 1 shows the test on the main winding only. Figure 2 shows the test on the combined main and starting winding single phase. Figure 3 shows test on

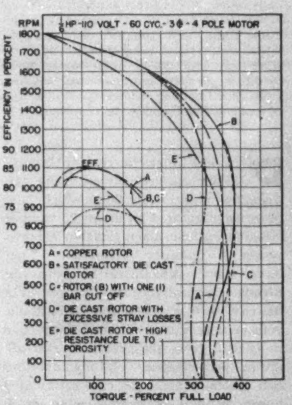

Figure 3. Speed-torque and efficiency curves of polyphase motor with typical cases of satisfactory and defective die-cast rotors and copper-cage rotors

Same rotors as Figures 1 and 2

three phase. Note the reduction in pull-up and breakdown torques and the efficiency caused by excessive stray load losses as shown by curve *D*. These curves were all produced by the motor driving a dynamometer. The stray load losses were so great in the motor (represented by curve *D* in Figure 1) that the torque was zero at approximately 630 rpm, and then the dynamometer drove the rotor.

The effect of excessive rotor resistance is shown by curves E in Figures 1, 2, and 3.

Figure 4 illustrates how the efficiency and torques vary with stray load losses. These curves represent the average values from tests on several hundred die-cast rotors, compared with average copper rotors of a certain design set up as 100 per cent. The curve of the torque at 600 rpm is shown because it is used as a test control point for this particular design of single-phase motor. When the breakdown torque on the main winding and the torque at 600 rpm on the combined winding are of acceptable values, the balance of the speed-torque curves are usually satisfactory. If the rotor resistance is excessive, the breakdown torque is usually too low.

Reduction of Stray Load Losses

The real problem with die-cast rotors resolves itself into eliminating, or at least reducing to a practical minimum, the eddy current and hysteresis losses in the laminations, eddy current losses in the rotor cage winding, and the short circuits between the conductor bars caused by contact between the conductor bars and the bare edges of the laminations. All of this is necessary to maintain the desired performance and eliminate rejects in the factory. A discussion of the means to accomplish the desired results follows.

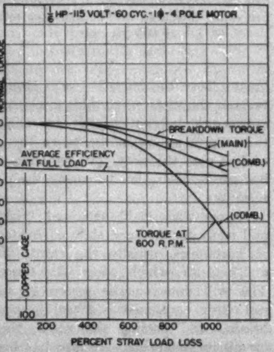

Figure 4. Torques and efficiency versus per cent of stray load losses with copper-cage rotors as 100 per cent

Design of Rotor

The design engineer may have either a program of superseding copper cage rotors with die-cast rotors or a new line of motors to design.

Die-cast rotors usually use pure aluminum or various aluminum alloys, depending upon the applications. Pure aluminum has a conductivity of approximately 60 per cent as compared to copper, but has only about 50 per cent conductivity when die cast. Therefore, in the laminations of a copper cage design, the pure aluminum conductor resistance is greater than for the copper bars. To have the same total resistance as for copper, the end rings must be of larger section than the copper rings. It may be an advantage in some cases to redesign the lamination to obtain a larger slot and also to decrease the tooth flux density.

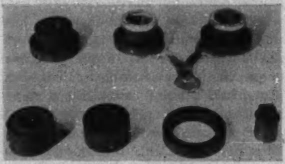

Figure 5. Sequence of operations in die-casting rotors

In a new design motor the slot combination of both stator and rotor may be changed to the advantage of the rotor, but again the designer should be very cautious about changing slot combinations, especially if he has a satisfactory fundamental line of combinations, since such a change may result in noise and cusps in the speed torque curve. However, conditions may be such that he can increase the diameter of the rotor and bore of the stator, and obtain the desired performance and cost without throwing the mechanical design of the motor out of line with standard sizes.

Larger slots, properly shaped, reduce the resistance and the high-frequency losses in the conductors. They also cause a reduction in the size of end rings, thus reducing the leakage losses. Lower teeth densities also will reduce the losses.

If the end rings are too large in section, they may cause casting difficulties and be more porous than small sections. Porosity means higher resistance. Large sections also increase the leakage between the rings and stator winding.

Figure 6. Front half of a die-casting mould

If the end rings are too thin, the cooling strains may cause a separation from the conductors. For motors that require cooling fans, there are further savings in cost by casting fan blades as a part of, and located at the end of, the rings.

For balancing the rotor, lugs can be cast onto the rings, and weights fastened to the lugs as required. A die-cast rotor should maintain its balance indefinitely whereas a copper-cage rotor may not. This is because the copper conductors do not fill the slot and may shift position a slight amount to change the balance. Recent improvements in copper-cage rotors have reduced this condition considerably, however, in die-cast rotors, the slots are filled solidly and therefore, no shifting can occur.

Processing of Rotor Laminations

The proper maintenance of the lamination dies will keep the punching strains and burrs to a minimum thus resulting in lower hysteresis and eddy current losses.

The eddy current losses can be reduced further by insulating the lamination surfaces to obtain sufficient interlamination resistance and to provide insulation between the slot walls and the die cast conductor bars. The insulation should be such that it will not be injured by the high temperature required for die casting, or forced out by the casting material. There are different methods of obtaining this insulation. The motor application may have some bearing upon the type of insulation used.

Strain relieving will reduce the hysteresis losses and increase the permeability of the steel.

Figure 7. Rear half of a die-casting mould

Die Casting Methods

There are two common methods of die casting rotors, namely, the closed-mould or high-pressure type and the end mould or "dunking" type. The centrifugal type is sometimes used, but is not as commonly used as the above types.

In the first type, the rotor core is placed into a 2-part mould and the mould closed. Hot metal is forced into the part of the mould which forms the rings and into the slots and then allowed to cool sufficiently to solidify the metal before removing the rotor. A close clearance between the mould and outside diameter of the rotor is desirable. A shoulder in the die at each end of the mould will eliminate any flash of metal around the outside of the rotor. A closed-slot rotor has advantages over a partially-open-slot rotor. There must be enough pressure against the laminations to prevent the hot metal from being forced between them and around the outside of the rotor. If this occurred, the eddy current loss would be increased. However, the pressure should not be so great that it will increase the eddy current losses.

In the closed-mould method rotors may be cast either singly or in multiples of six or more depending upon the size of the rotor and the size of the equipment. Rotors may be cast on special hubs or quills, or shafts if the production warrants it. However, means must be provided to prevent any of the laminations from moving and closing off the slots.

Figure 5 shows the different stages of a rotor from the laminations to the cast rotors. Figures 6 and 7 show the two halves of a typical mould with the rotor core assembled into one half of the mould ready to cast. Figure 8 shows a high-pressure die-casting machine.

In the end mould or dunking method, for small rotors the stack of laminations is assembled onto an arbor with a head on one end, or fastened to one end ring mould. There is a spiralled key on the arbor to skew the laminations, which cannot move when once assembled. End ring moulds are assembled to each end of the stack of laminations and the whole assembly tightened by a nut on the arbor. Unless properly controlled by using a torque indicator or torque wrench when tightening the nut, there may be excessive pressure exerted between laminations which will increase the eddy current losses. The normal frequency loss would not amount to very much but there can be considerable loss at tooth pulsation frequencies. The assembled unit is then placed into a well into which hot metal has been poured. The metal is forced under pressure through the ports in the lower ring mould, then into the slots and upper end ring mould. Ports in the upper mould permit the air and gases to pass through them.

The type of equipment, the pressures, temperatures, type of moulds, and gating of the moulds are very important to both methods of die casting in reducing the porosity and broken bars to a minimum.

The elimination of impurities in the die-cast metal results in more solid sections of the cast cage winding. This may be done by using nonmetallic linings for the melting pots and ladles.

Machining Rotor Surface

After the die-casting operation, the outside surface of the rotor is machined or ground to the proper finished diameter. For the motor's performance, grinding the outside diameter is generally more satisfactory for closed slots. Machining this surface results usually in higher stray load losses than by grinding. This is because the machining is more concentrated and drives the bridge or tooth tips into the conductor bars resulting in higher stray load losses. Grinding is generally unsatisfactory for partially-open-rotor slots as the grinding wheel may pick up too much die-cast metal and clog the wheel.

Heating the completed rotor at a reasonably high temperature, followed by proper cooling after machining or grinding the rotor surface, will break the conductor bars away from the slot wall and tooth tips or bridges. This process also breaks loose the burrs between laminations at the surface and adds some oxide between the laminations. It also relieves the strains set up in the tooth tips or bridges over the slots, thus reducing the hysteresis losses and increasing the permeability.

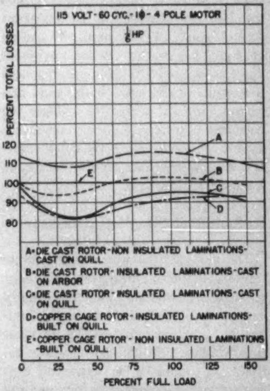

Figure 9. Per cent of total losses versus per cent load for various methods of processing die-cast rotors compared with copper-cage rotors as 100 per cent

Rotors with highly stressed bridges and teeth, for instance, show up hysteresis harmonics, usually the third, fifth and seventh, which affect the torque. This will show on the screen of special test equipment. After properly heating and cooling the rotor, these harmonics disappear. It also has been found that the conductivity of the material in the cage winding has been increased.

Figure 8. Die-casting machine using moulds in Figures 6 and 7 to die cast the rotors in Figure 5

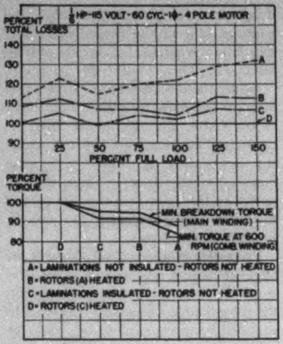

Figure 10. Upper curve is per cent of total losses versus per cent load for die-cast rotors with various processing

Lower curve shows the breakdown and torque at 600 rpm for the same rotors as above plotted against the process

Results Due to Processing

The results of various processes are shown in Figure 9 and compared with copper-cage rotors, *E*, which are considered as 100 per cent. Curve *A* shows die-cast rotors whose laminations and slots have not been insulated. Curve *B* is for die-cast rotors with laminations and slots insulated, assembled upon an arbor and locked in place with a nut ready for die casting. The higher losses are due to excessive pressure as compared to curve *C* whose laminations were insulated and assembled onto a quill. Curve *D* shows copper-cage rotors whose laminations were insulated. All laminations for the rotors shown by these curves in Figure 9 were made from the same lot of steel, and punched with the same dies.

There are four conditions shown in Figure 10: the laminations not insulated and not heated after machining; rotors heated to reduce the losses; laminations insulated but not heated; and the rotors heated. The upper set of curves show the per cent total losses plotted against per cent of full load for the different processes. Since process *D* was adopted for standard, it is set up as 100 per cent.

The lower curves in Figure 10 show the effect of the various processes upon the breakdown torque on the main or running winding and the torque at 600 rpm on the combined winding. The process *D* is considered as the standard and the minimum torques permissible are considered as 100 per cent. The lines between the points are connecting lines only to show the trend of results. All curves in Figure 10 are from results on die-cast rotors with a different type and gauge of steel than used in the previous tests.

The curves shown in Figure 11 are for the same die-cast rotors as Figure 10. The dotted lines are for the minimum, average, and maximum torque values at 600 rpm on the combined winding observed throughout the range of the lot tested, and are in per cent against the different processes. The minimum torque permissible is considered as 100 per cent torque for the process *D*. The solid lines show the corresponding stray-load losses obtained by testing the same rotors in a 3-phase stator. The type of service to which the motor will be subjected will determine whether or not it is necessary to insulate the rotor laminations and slots or heat the rotors after finishing the surface.

The results due to the number of times the rotors of a certain design are heated are shown in Figure 12. The rotors were all insulated prior to die casting. The condition where the rotors were not heated is considered as 100 per cent. When heated once the stray-load losses average about 72 per cent of the stray-load losses with no heating. The maximum improvement in the reduction with one heating shows a value of about 56 per cent of the value with no heating. There are sometimes instances where the burr condition of the laminations is very bad, in which case several heatings may be necessary. It has been found that there is very little improvement to be gained by heating the rotor more than three times unless there is a marginal case.

The per cent of total losses versus per cent full load for various processes is shown in Figure 13 for die-cast rotors operated as 3-phase motors. The rotors tested are the same rotors as shown as single-phase motors in Figure 9 and compared with the copper-cage rotors which are considered as 100 per cent.

Testing Die-Cast Rotors

Accuracy and consistency of test methods, equipment, and personnel are essential to reliable results during the development stage and for production testing. A satisfactory procedure for the development stage consists of using a standard single-phase stator and a 3-phase stator for checking performance and stray-load losses. These stators are kept as laboratory standards to check die-cast rotors of a given design.

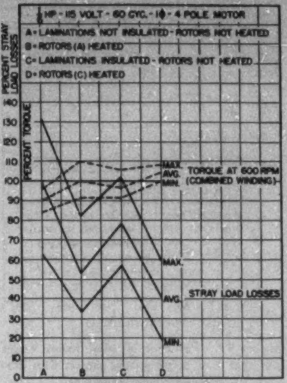

Figure 11. Per cent of stray-load losses and torque at 1/3 synchronous speed for the various processes of die-cast rotors

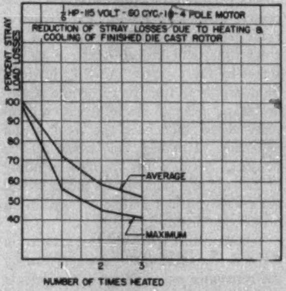

Figure 12. Reduction of stray-load losses due to heating the finished die-cast rotors

The stator and rotor are mounted in a frame in such a manner that the rotor is overhung from two ball bearings spaced apart sufficiently to maintain a uniform air gap. The frame is open on the one end as there is no end bracket. This makes it convenient to assemble rotors with uniform results. The bearing friction is maintained at about three watts for a 1/6 horsepower motor.

Rotors are checked for stray-load losses on 3-phase and correlated with the single-phase performance. Usually hundreds of rotors are tested so as to obtain minimum, average, and maximum values. There are then sufficient data for establishing limits and other data for production testing.

Many methods have been investigated but the foregoing method which is checking stray-load losses by the reverse-rotation method proved to be the most accurate and the fastest for both develop-

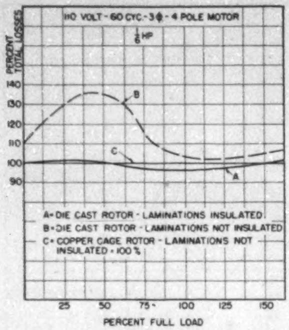

Figure 13. Per cent of total losses versus per cent load of polyphase motors with die-cast and copper-cage rotors

ment and production testing. By this method a production testing rate of 150 rotors per hour has been attained. Excessive stray-load losses, and excessive rotor resistance, insufficient skew of the rotor slots, and broken bars can be detected by this method. Actually it would be desirable to test the rotor in a standard stator prior to assembly into a complete motor and check the torques and efficiency. However, this would not be practical because the starting winding in the case of a single-phase motor would get excessively hot and soon burn up on production testing.

Testing rotors by the locked saturation method is satisfactory for measuring the resistance only. Most of the defects are due to stray-load losses. To check them the rotor must be revolved. However, a method for checking broken bars and high resistance is discussed at the end of this paper.

The production equipment consists of a polyphase, ball bearing motor driving the rotor to be tested through a shaft and coupling mounted on outboard ball bearings. The test stator has the same number of slots as the standard stator but oversize to reduce the heating. This equipment is shown diagrammatically in Figure 14. A rotor that represents the minimum acceptable performance is used for a standard. The watts input of the driving motor is correlated with the driving torque and stray load losses and the current in the test stator circuit determines whether the resistance of the rotor is excessive due to porosity or broken bars, in which case it will be lower than normal and it will be higher than established limits if the slots are not skewed the proper amount.

Figure 15 shows split-phase motor speed-torque curves, both positive and negative speeds, for a satisfactory and a defective rotor.

Figure 16 shows similar curves for a polyphase motor except that a rotor with a broken bar and another with excessive resistance are shown.

The method of calculating the stray-load losses of fractional horsepower motors was derived from data taken for the various known methods of calculating stray-load losses. It is also necessary to properly proportion the various losses, so that corrective measures can be applied to the processing of the rotors. The stray-load losses may be grouped according to the AIEE standard for polyphase motors.[19] Changed core loss and high frequency I^2R due to changed magnetic fields is the important item in moderate size motors.

Reverse Rotation Method of Determining Stray-Load Losses

The basis for these measurements was first taken from published works. However, refinements were made for this particular problem.

To outline briefly, the above consisted of applying a balanced polyphase voltage across the stator terminals and driving the rotor in the opposite direction to that of the revolving field. The stator input power, current, and stator resistance are measured during the test.

Denote the stator input by W_s.
Denote the stator copper loss by W_{cu}.
Denote the net stator input by W.
Let $W = W_s - W_{cu}$.

By means of a dynamometer, the rotor driving watts (P_r), and friction and windage (P_f) of the dynamometer and motor are measured. The net driving watts $= P$. Then, $P = P_r - P_f$.

Figure 14. Schematic diagram of reverse rotation method of testing die-cast rotors for stray-load losses

Under these conditions the total power input is consumed in losses. In the case of the stator, the total power input W, consists of stator copper loss and power supplied to the rotor for part of the rotor double-frequency losses. The mechanical power to the rotor also supplies part of the rotor double-frequency loss and the tooth-frequency losses.

From the relation $R = R_2(1-s)/s$ we have at minus synchronous speed, $R = -1/2\ R_2$ which shows that one half (1/2) the rotor double-frequency losses must be supplied by mechanical power, while the other half must be supplied by the stator. Therefore, if we subtract the net stator power from the net driving watts, P, we have left the tooth frequency losses, or stray load loss $= P - W$.

At 1/2 synchronous speed in reverse direction from $R = R_2(1-s)/s$ we have $R = -1/3R_2$ which means that the mechanical power supplies 1/3 of the rotor loss due to the fundamental frequency and 2/3 the power supplied by the stator. Therefore, if we multiply the net stator input by per cent of synchronous speed, in this case 50 per cent, we have the net stator input $(2/3) \times 50$ per cent $= 1/3$ which is equal to the fundamental losses supplied by mechanical power.

By substituting the two values we again have stray-load loss, or for any speed, we have stray load loss $= P - W \times$ per cent synchronous speed.

Segregation of Eddy-Current and Hysteresis Losses

Stray load losses are caused by several factors. There are only two ways in which this power can be consumed, by eddy current, and by hysteresis losses. Since any increase in these losses at fundamental frequency is taken out in calculation of stray load loss, all we have left are these losses at tooth pulsation frequencies. Eliminating the design constant from the formulas for eddy current and hysteresis losses we have the equation for hysteresis loss

$$P_h = B^n f$$

and for eddy current loss

$$P_e = B^2 f^2$$

In these equations the machine constants are taken out since they are the same in the same machine.

Now let us take the measured stray loss at normal voltage and at minus

1,800 rpm, (assuming a 4-pole motor). We can then take this loss as made up of tooth pulsation eddy current and hysteresis loss, or

$$P_h+P_e=\text{stray load loss at minus } 1{,}800 \text{ rpm} \quad (1)$$

If we keep the flux density constant, and by regulating the voltage and dropping the speed to minus 900 rpm, the tooth pulsation frequency is half, therefore, we can set up equation 2

$$0.5\,P_h+0.25\,P_e=\text{stray loss at minus } 900 \text{ rpm} \quad (2)$$

in terms of equation 1.

Solving equations 1 and 2 simultaneously we get P_h and P_e at minus 1,800 rpm. From these values P_h and P_e can be calculated for any speed at this flux density.

For greater accuracy, the stray loss can be taken for any two speeds. For example, for minus 1,800 rpm and minus 900, the equation would be the same as equations 1 and 2.

The same thing could be done by holding the frequency constant and changing the flux density if the constant, n, in the hysteresis loss equation were known. However, Steinmetz's determination of the constant $n=1.6$ does not always apply to present-day materials. We have found that for present-day materials the constant n varies from 1.5 to 3.0 and it may not be constant for a given material. Thomas Spooner in his book[11] reported a similar range. The Massachusetts Institute of Technology staff[10] has done considerable work along this line and they report a value for this constant n varying from 1.5 to 2.5.

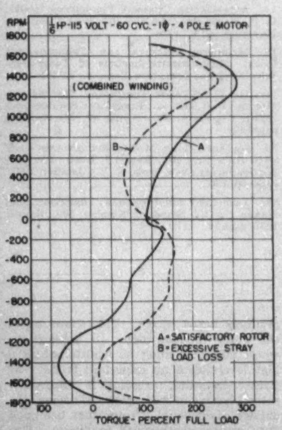

Figure 15. Positive and negative speed-torque curves of single-phase motors with die-cast rotors

Two examples of segregating the hysteresis and eddy-current losses are as follows for speeds of minus 900 and minus 1,800 rpm. The same stator was used with different die-cast rotors.

One motor had 155 watts stray-load loss at minus 1,800 rpm and 73 watts stray-load loss at minus 900 rpm. Let

$$P_h+P_e=155 \text{ watts at minus } 1{,}800 \text{ rpm} \quad (3)$$

$$0.5\,P_h+0.25\,P_e=73 \text{ watts at minus } 900 \text{ rpm} \quad (4)$$

which can be written

$$P_h+0.5\,P_e=146 \text{ watts} \quad (5)$$

Solving by subtracting equation (5) from equation (3)

$$0.5\,P_e=9 \quad (6)$$

$$P_e=18 \text{ watts or } 11.6 \text{ per cent of the total stray load loss} \quad (7)$$

Then

$$P_h=137 \text{ watts or } 88.4 \text{ per cent of the total stray load loss} \quad (8)$$

Another motor had 185 watts stray load loss at minus 1,800 rpm and 60 watts at minus 900 rpm.

Then

$$P_h+P_e=185 \text{ watts at minus } 1{,}800 \text{ rpm} \quad (9)$$

$$0.5\,P_h+0.25\,P_e=60 \text{ watts at minus } 900 \text{ rpm} \quad (10)$$

which can be written

$$P_h+0.5\,P_e=120 \text{ watts} \quad (11)$$

Solving by subtracting equation 1 from equation 9

$$0.5\,P_e=65 \quad (12)$$

$$P_e=130 \text{ watts or } 70.2 \text{ per cent of the total stray load loss} \quad (13)$$

Then

$$P_h=55 \text{ watts or } 29.8 \text{ per cent of the total stray load loss} \quad (14)$$

It is to be noted that the first motor had a high percentage of hysteresis losses whereas the second motor had a high percentage of eddy-current losses.

Stationary Method for Checking High Resistance and Broken Bars in Die-Cast Rotors

It is important for development work with die-cast rotors to be able to detect broken bars quickly and also to serve as a check for the people on production testing. It is also desirable to detect high resistance and the location of the high-resistance bars or high-resistance sections of the resistance rings of the rotor. The equipment shown in Figures 17 and 18 perform such duties as mentioned before.

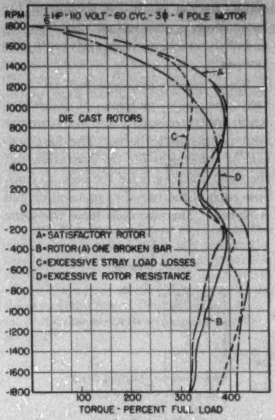

Figure 16. Positive and negative speed-torque curves of polyphase motors with die-cast rotors

times the slot pitch. A section of the laminations is removed entirely near the end of the stack, dividing each tooth into two parts.

Brass spacers are arranged to separate the two sections of stackings which are bolted solidly into one structure with nonmagnetic bolts. The long section of stacking is for the excitation and the short stacking is for the pick up coils. Into each of the two slots an exciting coil is placed. The two coils have the same number of turns wound in the same direction and connected in series to a low, adjustable voltage, 60-cycle source, with an ammeter to measure the current.

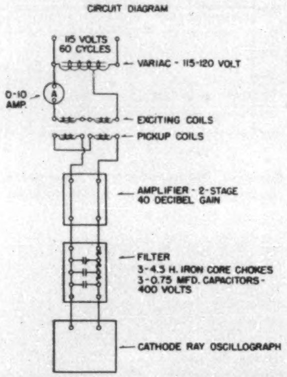

Figure 18. Circuit diagram of apparatus shown in Figure 17 plus the auxiliary equipment

The two pick-up coils are connected in series, but opposing, to a 2-stage amplifier of 40 decibels gain. The output of the amplifier is connected through a low pass filter, with cut-off frequency below 180 cycles to a cathode-ray oscilloscope. A rotor to be tested is placed on rollers so arranged that the standard air gap, as a motor, is maintained. A micrometer screw is used to adjust the position of the stator to make the air gap uniform for both sets of teeth. The exciting current is adjusted; the oscillograph sweep frequency is synchronized with the supply voltage so that one full wave of the differential pick-up voltage can be seen on the screen.

The rotor is turned slowly and variations of amplitude of this voltage observed on the oscilloscope. As the rotor is turned into a position of maximum coupling between two of its bars and exciting coils, the pattern on the oscilloscope is essentially a sine wave whose amplitude is adjusted to a convenient value by means of the gain control. An amplitude of about 1/4 of a full 5-inch screen is suitable. As the rotor is turned through the distance of one slot-pitch, the amplitude decreases a small amount and then returns to the same value as successive bar pairs pass through the maximum coupling position, provided the rotor bars are uniformly good and the equipment is in proper adjustment.

When a complete open bar passes the test position the amplitude increases momentarily by 250 to 400 per cent as the bar passes one coil and decreases or reverses as the bar passes the other coil, the total change in the second case being of about the same amount as in the first. Even though the rotor is turning quite rapidly this momentary increase of amplitude is observed readily. When a porous bar, whose resistance is considerably greater than normal, passes the test position the same effect is observed, the amount of deflection being less and dependent upon degree to which the porosity or flaw has increased the resistance of the bar relative to other bars on the same rotor.

If the rotors have been machined before testing, the presence of eccentric machining is evidenced by a gradual change of amplitude, maximum peak values appearing as that side of the rotor having more material removed passes the test coils.

Discussion

W. R. Bennet (Westinghouse Electric Corporation, Lima, Ohio): In some instances, it is desirable to replace a copper-cage rotor by an aluminum die-cast rotor. Larger end rings are, of course, required in the die-cast rotor and due to space limitations within the motor the end rings cannot always be made symmetrical. This means that one ring may have to be much thicker than the other to get the desired rotor resistance. I have had a case where one ring was made four times thicker than the other, but the performance of the die-cast rotor was in no way affected and equalled the performance of the copper-cage rotor. I know that Packer has had similar experiences in his design of die-cast rotors.

It has also been my experience that grinding the outside diameter of the die-cast rotor produces better rotors. This shows up in the motor performance. In applications where efficiency must be maintained at a high level this is an important factor. As Packer indicates, grinding is limited to rotors having closed slots. Turning the outside diameter of a rotor that has open slots, creates another bad condition. Aluminum particles are carried around the surface of the rotor by the turning tool; unless this aluminum is removed by heating, the result will be a motor with lower efficiency.

Various heat treatments are used on completed rotors to improve the motor performance. In some cases flame treatment for approximately one minute gives the desired result. This process consists of using oxygen and acetylene gas to give an intense heat; and revolving the rotor through this flame. This method is generally used on integral horsepower rotors. Heating rotors in an oven at the proper temperature gives good results for fractional horsepower rotors. I agree with Packer that the process of heating the rotor after machining is generally of such benefit that it should be seriously considered for die-cast rotors.

L. C. Packer: Bennet is correct relative to cases where one end ring may be much heavier on one end than the other. I have seen rings on one end from 25 to 50 per cent of the thickness at the other end and as thin as 1/8 inch for $3^{3}/_{4}$-inch diameter and as thin as 3/16-inch thick on about 5-inch diameter rotors. It is my understanding that no casting troubles are encountered with either of them, although fan blades are cast integral with each of them. The design will determine the practicability of thin section rings.

Grinding the outside diameter of rotors is generally limited to closed slot rotors as stated by Bennett and produces better rotors than those machined by ordinary methods. It might be added here that some recent experiments with shaving the outside diameter of closed-slot rotors has also produced some excellent results, but not enough of them were produced to permit drawing any definite conclusions.

The heating of the complete finished rotor has proved to be a necessity in order to produce uniformly good rotors. The method of heating employed depends a great deal upon the design, application, and factory conditions.

The greatest benefit from heating is derived by breaking the conductor away from the iron. The stray-load losses due to tooth pulsation frequencies and total 60 cycle iron losses are reduced in most cases. The rotor resistance is also reduced due partly to an increase in the conductivity of the aluminum after heating and also to breaking the conductors away from the iron. The short circuit and magnetizing reactances are in most cases increased slightly which reduces the magnetizing current. In some cases the magnetizing current has been increased due to too much oxidation, thus decreasing the sections of some of the magnetic paths.

A thin film of aluminum adhering to the surface of a finished rotor will reduce the breakdown, pull up, and in some cases the starting torque. The degree of the harmful effects depends upon the thickness and continuity of the film. This film must be removed if the motor is expected to perform properly.

Armature Iron Losses in Series Motors

SHELDON S. L. CHANG
STUDENT MEMBER AIEE

J. H. KARR
MEMBER AIEE

IN ORDER to calculate the performance of a-c series motors, it is necessary to predict the amount of iron loss as well as the way in which it is supplied. Tests results show that there exists a discontinuity in the armature iron losses supplied electrically and mechanically. The phenomena can be explained satisfactorily by the double revolving field theory.

Experimental

In order to illustrate experimentally the effect of speed (and rotor frequency) on iron loss distribution, a bi-polar series motor, rated at 1/3 horsepower, 5,000 rpm, was driven over a wide speed range for each of several selected values of excitation. The circuit arrangement for obtaining the data of Figures 1 and 2 is shown in Figure 3. Brushes of motor (B) were removed.

The wattmeter in the circuit of motor (B) reads field I^2R, field iron loss and that part of the armature iron loss supplied by the field. Figure 1 shows this input less field I^2R plotted against speed for several excitation values. Note the two regions on each curve showing essentially constant input, and the sharp reduction in the vicinity of 3,600 rpm.

Several general conclusions can be drawn from this. First, iron loss supplied by the field for given excitation is independent of speed (hence of armature frequency) for all speeds below and above synchronous speed. This means that no variable frequency armature iron loss is furnished by the field. Second, a constant component of field iron loss must be furnished by some other source than the field for speeds above synchronous.

Motor (A) in Figure 3 was calibrated so that the torque which the motor develops for any input and speed could be read from calibration curves. Thus, by reading the input to motor (A), the torque required to overcome friction and windage and armature iron loss of motor (B) can be obtained for various values of excitation and speed. These data are plotted in Figure 2. Note the abrupt rise in torque required in the region of synchronous speed.

Analysis

Consider the pulsating flux set up by the stator as being the result of two flux systems rotating at synchronous speed in opposite directions in accordance with the familiar double revolving field theory of the induction motor. Iron losses in the armature will then result from frequencies of $(f_r - f)$ and $(f_r + f)$, in which f_r is the frequency corresponding to armature speed and f is line frequency. Thus, at 2-pole synchronous speed $f_r - f = 0$.

The rotor of an ordinary polyphase induction motor revolves in the rotating, circular field at nearly synchronous speed. Rotor iron loss is neglected usually since the rotor frequency is very low.

If, however, the rotor revolves for any reason at a materially different speed in either direction relative to the revolving field, the rotor iron loss is no longer negligible. The rotor iron loss can be considered as a component of rotor current in stator terms, but not supplied necessarily by the stator. Let this component of current be $I_{r(h+e)}$. Then the actual rotor iron loss is

$$W_r = I_{r(h+e)} E_r \tag{1}$$

Where E_r is the voltage generated in the rotor in stator terms due to the air gap flux.

The stator air gap voltage E_s will be different than the rotor air gap voltage, E_r, because stator and rotor frequencies are, in general, not equal. Thus

$$E_s = E_r \frac{f}{f \pm f_r} \tag{2}$$

The rotor loss supplied by the stator will then be

$$W_F = I_{r(n+e)} E_s = I_{r(h+e)} E_r \frac{f}{f \pm f_r}$$
$$= (\text{actual rotor iron loss}) \frac{f}{f \pm f_r} \tag{3}$$

The remainder of the rotor iron loss must be supplied from the mechanical energy of the rotor, or act as a load on the rotor. Thus, the loss supplied by the rotor is

$$W_A = (\text{actual rotor iron loss}) \left(1 - \frac{f}{f \pm f_r}\right)$$
$$= (\text{actual rotor iron loss}) \left(\frac{\pm f_r}{f \pm f_r}\right) \tag{4}$$

in which the (−) sign is for the forward revolving field and the (+) sign is for the backward revolving field.

Let

W_{H+} = hysteresis loss in armature due to forward revolving field
W_{H-} = hysteresis loss in armature due to backward revolving field
W_{E+} = eddy current loss in armature due to forward revolving field
W_{E-} = eddy current loss in armature due to backward revolving field
W_{HO} = hysteresis loss in armature at zero speed
W_{EO} = eddy current loss in armature at zero speed

Then

$$W_{H+} = \frac{W_{HO}}{2} \left|\frac{f_r - f}{f}\right| \tag{5}$$

$$W_{H-} = \frac{W_{HO}}{2} \left|\frac{f_r + f}{f}\right| \tag{6}$$

$$W_{E+} = \frac{W_{EO}}{2} \left(\frac{f_r - f}{f}\right)^2 \tag{7}$$

$$W_{E-} = \frac{W_{EO}}{2} \left(\frac{f_r + f}{f}\right)^2 \tag{8}$$

Combining equations 3, 5, 6, 7, and 8, the expression for the armature iron loss

---

Paper 49-70, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted June 9, 1948; made available for printing December 20, 1948.

SHELDON S. L. CHANG and J. H. KARR are with Robbins and Myers, Inc., Springfield, Ohio.

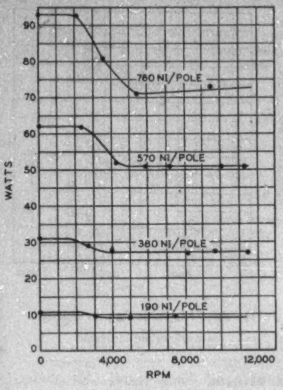

Figure 1. Effect of speed and excitation on field input

supplied by the field for $f_r > f$, that is, speed above synchronous, is

$$W_F = \left[\frac{W_{HO}}{2}\left(\frac{f_r - f}{f}\right) + \frac{W_{EO}}{2}\left(\frac{f_r - f}{f}\right)^2\right]\frac{f}{f - f_r} + \left[\frac{W_{HO}}{2}\left(\frac{f_r + f}{f}\right) + \frac{W_{EO}}{2}\left(\frac{f_r + f}{f}\right)^2\right]\frac{f}{f + f_r} = W_{EO} \tag{9}$$

Similarly, for $f_r < f$, the armature iron loss supplied by the field is

$$W_F = W_{HO} + W_{EO} \tag{10}$$

Combining equations 4, 5, 6, 7, and 8, the expression for armature iron loss supplied from mechanical energy of the armature, for $f_r > f$, is

$$W_A = \left[\frac{W_{HO}}{2}\left(\frac{f_r - f}{f}\right) + \frac{W_{EO}}{2}\left(\frac{f_r - f}{f}\right)^2\right]\frac{-f_r}{f - f_r} + \left[\frac{W_{HO}}{2}\left(\frac{f_r + f}{f}\right) + \frac{W_{EO}}{2}\left(\frac{f_r + f}{f}\right)^2\right]\frac{f_r}{f + f_r} = W_{HO}\frac{f_r}{f} + W_{EO}\left(\frac{f_r}{f}\right)^2 \tag{11}$$

Similarly, for $f_r < f$

$$W_A = W_{EO}\left(\frac{f_r}{f}\right)^2 \tag{12}$$

It will be seen that equations 9, 10, 11, and 12 are substantiated in a general way by the test results of Figures 1 and 2.

The power represented by equations 11 and 12 act as loads on the motor in the form of magnetic drag. This drag torque becomes

$$T_d = \frac{112.7\ W_{HO}}{syn} + \frac{112.7\ W_{EO}}{syn} \times \frac{\text{RPM}}{syn} \quad \text{ounce foot for } f_r > f \tag{13}$$

or

$$T_d = \frac{112.7\ W_{EO}}{syn} \times \frac{\text{RPM}}{syn} \quad \text{ounce foot for } f_r < f \tag{14}$$

Calculations

In order to compare test and calculated data, it is necessary to have iron loss curves showing hysteresis and eddy current losses separately. Such a set of curves at 60 cycles is shown in Figure 4 and was obtained from conventional curves which showed total iron loss versus flux density for several frequencies.

The magnetization curve for the motor under consideration is shown in Figure 5. It is proposed to compare experimental and calculated results for excitations of 190, 380, and 570 ampere turns per pole. Armature tooth area per pole is 1.395 square inches and core volume is 1.29 cubic inches. Sine wave distribution of air gap flux is assumed although it is recognized that the actual wave shape may deviate considerably from this. The standstill armature iron losses are calculated in the manner used usually for single-phase induction motor, that is, divide polyphase iron loss by two. The justification for this is that there is essentially no flux in the cross axis. The method is equivalent to assuming sinusoidal space distribution of flux.

Calculated rotor hysteresis loss is shown in Table I. In accordance with the

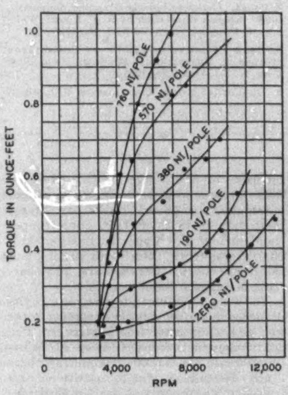

Figure 2. Friction and windage, and magnetic loading as functions of speed and excitation

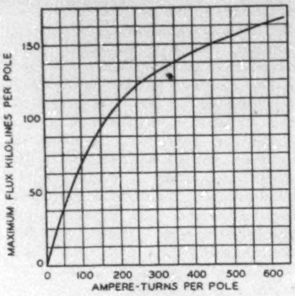

Figure 5. Magnetization curve

theory which has been presented, this is the amount by which the field input should be reduced in going through synchronous speed. These experimental values are shown in Figure 1 as well as in Table I.

The magnetic drag in the armature in terms of torque can be calculated from equations 13 and 14. As an example, for an excitation of 380 ampere turns per pole, this drag for speeds below 3,600 rpm is

$$T_d=\frac{112.7\ W_{EO}}{syn}\times\frac{\text{RPM}}{syn}$$

$$=\frac{112.7\times 2.42\times \text{RPM}}{(3{,}600)^2}=21\times 10^{-6}\times \text{RPM}$$

For the same excitation, and speeds above 3,600 rpm, the drag is

$$T_d=\frac{112.7W_{HO}}{syn}+\frac{112.7W_{EO}}{(syn)^2}\text{RPM}$$

$$=\frac{112.7\times 5.375}{3{,}600}+\frac{112.7\times 2.42\times \text{RPM}}{(3{,}600)^2}$$

$$=0.168+21\times 10^{-6}\times RPM$$

Likewise, the magnetic drag of 190 ampere turns and 570 ampere turns can be calculated:

190 Ampere Turns	
R.p.m. < 3,600	$T_d=9.05\times 10^{-6}\times$r.p.m.
R.p.m. > 3,600	$T_d=0.0504\ 9.05\times 10^{-6}\times$r.p.m.
570 Ampere Turns	
R.p.m. < 3,600	$T_d=32.1\times 10^{-6}\times$r.p.m.
R.p.m. > 3,600	$T_d=0.308\ 32.1\times 10^{-6}\times$r.p.m.

The foregoing results are plotted in Figure 6. Experimental data are shown by circled points. Experimental data shown in Figure 6 are deduced from the data of Figure 2, using the zero ampere-turn curve on the latter as representing friction and windage.

Discussion

A. F. Puchstein (The Jeffrey Manufacturing Company, Columbus, Ohio): This paper is useful to set the stage for experimental and calculation techniques which will lead to more satisfactory procedures in predicting such losses.

It would have helped if the tests had been repeated also at other frequencies, as 25 cycles, and on larger motors, using a sensitive torque dynamometer. The paper confirms the existence of the near-discontinuity in the vicinity of synchronism, Figures 1 and 6. No light is thrown on the effect of slot openings, length of air-gap, or shape of pole shoe. Commutation effects are not considered. These introduce circulating currents and commutated-coil magnetomotive forces which change the value and phase relation of the field flux relatively to the field magnetomotive forces and so have some effect on the iron loss. The data reported do not include the effect of armature reaction, which tends to increase the iron losses. It is not stated whether correction or compensation was made for meter losses.

In the analysis, some use is made of polyphase induction motor theory. As of today the losses of such a machine are considered to be stator copper (fundamental and upper harmonics, skin-effect), stator core, stator tooth, stator tooth surface, rotor copper (fundamental and upper harmonics, skin-effect, rotor tooth, rotor tooth surface, and rotor core losses. Occasionally, eddy currents in adjacent metal masses.

The torque produced in the rotor is the resultant due to all rotor bar currents, rotor iron eddy, and rotor iron hysteresis. The last of these acts forward for speeds below synchronism and backward above synchronism. Tooth losses due to rotation act as a brake at all speeds and are supplied mechanically. Reluctance torques due to magnetic dissymmetries tend to balance out over a revolution. Similar losses are present in the series motor.

From the view point of the physics involved, it would clarify the problem if experiments and calculations were set up to determine the dependence of the iron losses upon the time rate of change of flux-density, both when this density varies as a straight line function of time and when it varies in other ways. This should be done for alternating and rotating fields and combinations of them. In such experiments, transient or other effects would probably be absent. It should then be possible to work out a method of loss calculation which fits the actual conditions more closely than the commonly assumed sinusoids.

L. C. Packer (Westinghouse Electric Corporation, Springfield, Mass.): This is a very interesting paper. All of the iron losses in this paper are based on no-load flux. Under load conditions these losses will change due to distortion caused by the armature flux when current flows through the armature winding. The changes may be compensating as the iron losses will be lower with current in the armature due to the armature flux bucking down the field flux, but the rotational losses might be increased by increasing the flux density in the teeth.

The losses in both the field and armature will generally be greater than when calculated from Epstein tests because the eddy current and hysteresis losses are increased by the punching of the laminations and may be as much as 1.5 to 2.5 times higher unless the laminations are annealed after punching. It is assumed generally that the hysteresis component of the iron loss varies directly with the frequency. Due to flux distortion or skin effect at higher frequencies and also to possible differences in depth of penetration, this assumption is probably not strictly

Table

RPM	Field Amperes	Test Value, Losses	Calculated Values P_e	P_h	Total
Rotational Losses on Direct Current					
2,000	7	4.45	0.89	3.54	4.43
4,000	7	11.0	3.56	7.1	10.66
6,000	7	18.7	8.0	10.6	18.7
8,000	7	28.4	14.2	14.1	28.3
10,000	7	40.0	22.2	17.7	39.9
12,000	7	54.8	32.1	21.3	53.7
14,000	7	69.4	43.7	24.8	69.1
16,000	7	85.4	57.1	28.3	85.4 (Base)
Rotational Losses on 60-Cycle Alternating Current					
6,000	7	11.63	5.47	8.2	13.67
8,000	7	19.5	9.7	10.9	20.6
10,000	7	28.8	15.2	13.9	28.8
12,000	7	40.0	21.9	16.3	38.2
14,000	7	49.8	24.8	19.1	48.9
16,000	7	60.7	38.9	21.8	60.7 (Base)

true and the hysteresis loss per cycle may be considerably higher at relatively high frequencies. However, this direct proportion to frequency may be close enough for indicating relative values of hysteresis and eddy current losses.

I think for equations 5 to 8 inclusive, it might be mentioned that these equations can be used only when you have the same ampere turns per pole as used for determining the values of W_{ho} and W_{eo}.

It seems to me that in equation 12, it should also contain the term $W_{ho}(fr/f)$. It does not seem possible that there will be no hysteresis loss between the points $fr=f$ and $fr=0$. Assuming a-c operation, there is the fundamental hysteresis and eddy current loss present at zero speed. This loss will decrease, however, in the tenth to zero at synchronous speed. However, the surface losses (with slotted primary or pole face losses in a salient pole motor) will increase with the frequency due to rotational speed.

One method of breaking down the armature iron losses into its two components of hysteresis and eddy current losses is to use test data for two speeds at the same ampere turns per pole. It is better to select speeds at which the readings are relatively large to reduce errors. In this illustration a 13,000-r.p.m. motor is used.

Table I of the discussion is divided into two sections, one each for direct and alternating current. On direct current the fundamental frequency is zero. Then the rotational losses should be a function of the speed from zero r.p.m. The calculated values in the a-c table are based on the assumption that the rotational losses are independent of fundamental frequency but depend only on speed to a zero speed base. Let

P_e = eddy current loss
P_h = hysteresis loss

Select from the d-c table the values of total iron loss at 10,000 and 16,000 r.p.m.

At 16,000 rpm

$$P_h+P_e=85.4 \tag{15}$$

At 10,000 rpm = 5/8 of 16,000 rpm

$$5/8P_h+25/64P_e=40 \tag{16}$$

P_h varies directly with frequency
P_e varies as the square of frequency

$$P_h+5/8P_e=64 \tag{17}$$

Subtract equation 17 from 15

$$3/8P_e=21.4$$
$$P_e=57.1$$
$$P_h=28.3$$

Apply the same method to the a-c data. For any speed at same flux

$$P_h=P_h(\text{at } 16{,}000 \text{ rpm})\times\frac{\text{rpm}}{16{,}000}$$

$$P_e=P_e(\text{at } 16{,}000 \text{ rpm})\times\frac{(\text{rpm})^2}{(16{,}000)^2}$$

The values at 2,000 and 4,000 r.p.m. were so low that they were inconsistent and inaccurate.

Chang and Karr are to be commended for their paper. There is very little literature on the subject in connection with Universal motors and more papers should be encouraged. A paper has been under preparation for sometime by me on this subject which, it is hoped, will be presented at some future date.

Sheldon L. Chang and J. H. Karr: The writers appreciate greatly the comments of Packer and Puchstein. Some of their comments are answered in the following:

Packer states that equation 12 should contain the hysteresis term $W_{ho}(f_r/f)$, while one of the main purposes of this paper is to show that it does not. The armature iron loss has a hysteresis component at all speeds, below or above synchronism. Equations 9, 10, 11, and 12 state that this armature hysteresis loss is supplied exclusively by the magnetizing ampere turns at speeds below synchronism, and that it acts as a mechanical load at speeds above synchronism. These equations are the logical consequences of the double revolving field theory and they are substantiated by test results of Figures 1 and 6.

Apparently the hysteresis loss does not obey the principle of superposition. The theory deviates from the test results in that the theory predicts an abrupt change at synchronism as shown by the solid lines while the test shows a relatively gradual change.

This near discontinuity has been verified in every a-c series motor we have tested and the writers suspect that the motor Packer mentioned is not an exception. Packer omitted the values at 2,000 and 4,000 r.p.m. for 60 cycle because they were so low and inconsistent. If these values follow Packer's equation they would not be much lower than the corresponding values in the d-c motor. If the same dynamometer were used in these tests the same degree of accuracy should hold.

Packer shows a very practical method of separating hysteresis and eddy current losses by test. His method is preferable after the first test motor is built. The writers are more interested in predicting the motor performance before the lamination die is made. After that you will have to take it for what it is anyway. The hysteresis loss and eddy current loss curves are based on our experience with a particular grade of steel. They are generally higher than the values given by the steel manufacturer as Packer pointed out. The values of W_{ho} and W_{eo} are calculated for the entire range of magnetization. In calculating the load points, W_{ho} and W_{eo} are the values corresponding to the net ampere turns in the axis of the main field. Usually the reluctance in the cross axis is very high.

In series motors with laminated but not slotted field, the surface loss is negligible. In series motors with slotted field, the surface values loss can be calculated as in induction motors. An additional term of $W_{eo}(f_r/f)^2$ should then be added to equation 11 and 12.

The wave shape or the harmonics have an appreciable effect on the armature iron loss. However the harmonics are not as important in the a-c series motors as in induction motors, with equally bad wave shape, because the armature current of the series motor is unaffected by the harmonic flux.

In very bad cases the distorted wave shape due to armature ampere turns may increase the armature iron loss 20 per cent. Assuming that the armature iron loss itself reduces the output torque by 15 per cent, the effect of wave shape amounts to 3 per cent of the output at most.

Puchstein suggested a very interesting way of determining the effect of wave shape. We feel that the experiments he suggested are carried out and the results are put into a form easily applicable to a-c series motor design that would certainly be a very valuable contribution.

Fundamental Theory of Inherent-Overheating Protection Under Running Overload Conditions

C. G. VEINOTT
FELLOW AIEE

L. C. SCHAEFER
ASSOCIATE AIEE

SEVERAL papers have been written giving quantitative test results on the application of motor protective devices. The object of this paper is to discuss the fundamental theory of such devices, and to show how this theory may be applied to the selection of protective devices for fractional horsepower motors. This fundamental theory has been developed and used over the course of the last 15 years in the application of disk-type thermostats to obtain built-in thermal overload protection. How well built-in overload protection can work has been attested by results published in a number of papers and articles on the subject. An understanding of the theory presented in this paper will, the authors believe, help the thermostat application engineer in selecting the right thermostat for any particular motor, and will help the user of the protected motor to understand better how and why the devices can work so successfully when properly applied.

Probably the first use of built-in thermal overload protection to small motors occurred in 1928, when a few applications were made on portable drill motors. Undoubtedly the first large-scale commercial use was on a popular make of hermetic refrigerators in 1929. In this case the thermostats were mounted on the compressor unit and were responsive to both temperature and current. They were revolutionary in another sense—they were automatic-resetting. Now, 19 years later, use of an automatic-resetting thermostat, mounted on the compressor, is common practice in the hermetic refrigeration industry. In 1930, disk-type thermostats were applied by one of the authors to fractional horsepower induction motors and used in a limited number of motors commercially. In 1933, the advantages of such protection were pointed out in a technical article.[1] Use of such motors has been increasing ever since, and will probably continue to increase. By 1939 the Underwriters' Laboratories had recognized the advantages and safety features of motors with built-in thermal overload protection. They coined the very descriptive phrase "inherent-overheating protection" and adopted standards covering such devices.[2]

Partly because disk-type thermostats appear to be replacing other forms of built-in protective devices for fractional horsepower motors, and partly because the authors' experience has been almost entirely with this type of device, the theory and discussion in this paper are centered around disk-type thermostats, although the same fundamental principles should apply equally well to all types of thermal protective devices used. Probably the best way to introduce this discussion of inherent-overheating protection is to begin with the theory of current-operated thermal devices which appear to be more generally understood.

Tripping Characteristics of Current-Operated Devices

Usual current-operated devices offer only over-current protection. A familiar example is the common circuit breaker with a thermal tripping element. A magnetic circuit breaker is responsive only to current, but under conditions of severe over-current, the device trips within a fraction of a second. Such characteristics are undesirable in fractional horsepower motors because temporary overloads or line transients may cause nuisance trip-outs. Thermally operated circuit breakers would be better because they introduce a time lag sufficient to overcome this objection. This time lag, or characteristic inverse-time tripping curve, is shown in Figure 1. Here, the vertical asymptote is the value of current which, if maintained indefinitely, will ultimately cause the circuit breaker to trip, theoretically, in infinite time. This value of current is commonly referred to as the "ultimate tripping amperes." The horizontal asymptote is at zero time and infinite current. In practice, the maximum value of current may be limited either by the rupturing capacity of the contacts if all the heat is generated in the bimetal element, or by the current-carrying capacity of the heating element, if one is used. Current-operated devices usually carry an ampere rating of the order of 83 per cent of the ultimate tripping current. Thus, the actual current necessary to trip such a circuit breaker, in infinite time, is approximately 120 per cent of its rating. Often, the effect of ambient is neglected in rating such devices. In fact, attempts are often made to nullify the effect of any change in ambient by setting the operating temperature of the thermal element very high, or by using differentially opposed elements, making the device responsive to rate-of-rise rather than to actual temperature rise.

In selecting a current-operated device to protect a given motor, the first step is to determine the motor current corresponding to the maximum permissible temperature rise. Then a circuit breaker having an ultimate tripping current

---

Paper 49-71, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted July 27, 1948; made available for printing December 28, 1948.

C. G. Veinott is manager of the induction motor section and L. C. Schaefer is a design engineer, both of the industrial engineering department, small motor division, Westinghouse Electric Corporation, Lima, Ohio.

equal to this value is applied. Thus this device tends to limit the temperature rise of motor, rather than to limit total winding temperature.

Tripping Characteristics of Disk-Type Thermostats

A disk-type thermostat, mounted in a section of a motor end shield, is shown in Figure 2. This device has the same familiar inverse-time characteristic as the conventional over-current thermal relay just discussed, but the inherent-overheating device is intentionally designed to have its tripping characteristic affected in a predetermined manner by ambient temperature. But that is getting ahead of the story. In Figure 3, the tripping characteristic curves of a typical disk-type thermostat are plotted for different ambient temperatures. It is to be noted that the ultimate tripping current is definitely a function of the ambient temperature. Consequently, to see better the effect of ambient temperature on ultimate tripping current, the ultimate tripping amperes have been plotted as a direct function of ambient temperature in Figure 4.

At this point it seems most appropriate to introduce a new term—"ultimate tripping ambient." The ultimate tripping ambient, at a specified current, is that value of ambient temperature which makes the specified current equal to the ultimate tripping current. That is, if the ultimate tripping current is 7.3 amperes at 35 degrees centigrade, the ultimate tripping ambient, at 7.3 amperes, is 35 degrees centigrade. At first, introduction of this new term may seem to serve no useful purpose, but it will be shown later how this term helps one to grasp and retain certain fundamental principles applicable to inherent-overheating protection. In part, the concept of this term originated from one laboratory method of determination of the ultimate tripping characteristics of a thermostat, that is by holding the current constant and very slowly increasing the ambient temperature until the thermostat trips. A more conventional way is to hold the ambient constant, measuring the tripping time, at different currents, thereby obtaining a characteristic curve at a particular ambient such as Figure 3. Either method can be used to obtain a curve such as Figure 4.

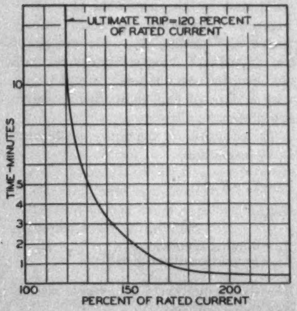

Figure 1. Time-current curve of thermally operated circuit breaker

Returning to Figure 4, it will be noted that the curve of ultimate tripping current versus ambient appears to be a parabola which, in fact, it is. Reason for the parabolic shape becomes more evident when the curve of rise of disk above ambient is plotted. The latter curve is obtained by subtracting the ultimate tripping ambient, for each current, from the disk-opening temperature. (The disk always opens at the same temperature, regardless of current or ambient temperature.) The temperature rise of the disk above its ambient is, of course, proportional to the watts generated in the thermostat, that is, to the I^2R losses. Hence, it is clear that the rise of the disk must be proportional to the square of the current, since the resistance of the nichrome heater is practically constant.

Now, the true interrelationship between ultimate tripping current, ultimate tripping ambient, and disk-opening temperature becomes apparent and we can create a word picture of this relationship as follows: Assume a given current of, say, 4.5 amperes to be passed through the thermostat continuously. The heater comes to a final ultimate temperature rise, heating the disk to a temperature somewhat below that of the heater. Say that the rise of the disk is 30 degrees centigrade above the thermostat ambient. Now, suppose the disk-opening temperature to be set at 120 degrees centigrade and further suppose that the ambient temperature of the thermostat be raised very slowly. This disk will always stay 30 degrees centigrade hotter than the ambient (assuming constant current, of course) so that when the ambient reaches 120–30 = 90 degrees centigrade, the disk will open. Hence, the ultimate tripping ambient for 4.5 amperes is 90 degrees centigrade for this thermostat. Or, in other words, the ultimate tripping current of this thermostat is 4.5 amperes at 90 degrees centigrade. Obviously, the ultimate tripping currents at other ambients can be determined similarly.

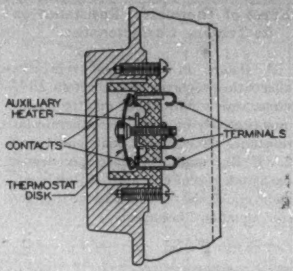

Figure 2. Cut-away view of disk-type thermostat mounted in motor end shield

Reduced to mathematical terms, the foregoing statements become

$$T_a = T_d - K_t I_u^2 \qquad (1)$$

where

T_d = disk-opening temperature
T_a = ultimate tripping ambient at current, I_u
I_u = ultimate tripping amperes at ambient, T_a
K_t = proportionality constant

Solving equation 1 for ultimate tripping current

$$I_u = \sqrt{(T_d - T_a)/K_t} \qquad (2)$$

Effect of Disk-Opening Temperature on Tripping Characteristics

Disk-opening temperature is, by itself a very important factor in inherent-overheating thermostats, because its value is a large factor in determining the effect of ambient upon tripping characteristics. In Figure 4, the disk-opening temperature was 120 degrees centigrade. Now suppose that the disk-opening temperature is raised, say 10 degrees centigrade. Then, at each value of ultimate tripping current, the ultimate tripping ambient is raised 10 degrees centigrade. This is a simple way to express the effect of disk-opening temperature on ultimate tripping characteristics.

The effect on the curve is to move the entire curve up 10 degrees centigrade, without changing its shape as has been done in Figure 5. This idea is expressed quantitatively in equation 1, and the effects of disk temperature on ultimate tripping current at a given ambient is expressed by equation 2.

To summarize: An increase or decrease of t degrees in the disk-opening temperature increases or decreases the ultimate tripping ambient at every current by t degrees.

Effect of Thermostat Resistance on Its Tripping Characteristics

A change in thermostat resistance affects the proportionality constant K_t in direct ratio. This effect may be shown quantitatively by introducing thermostat resistance directly into equations 1 and 2. If W_u equals the watts per degree centigrade rise of disk above its ambient, and r_t equals the resistance of the thermostat, equation 1 becomes:

$$T_a = T_d - (r_t/W_u)I_u^2 \tag{3}$$

and equation 2 becomes

$$I_u = \sqrt{(W_u/r_t)(T_d - T_a)} \tag{4}$$

From equation 4 it is apparent that the ultimate tripping amperes at a specific ambient will increase or decrease inversely as the square root of the change in thermostat resistance. This effect is shown graphically in Figure 6.

The constant, W_u, is a factor of thermostat design and is affected by the size and length of the heater element, by the relative location of the disk and heater element, by the apportionment of resistance between the heater and the disk, by the coefficient of radiation and absorption of the heater and disk materials respectively, and by the rate at which the heat is conducted from the disk by the electrical contacts and terminals. Outwardly, this appears to be quite an imposing list; however, many of the factors effecting W_u are constant within a particular line of thermostats and the determination of this constant is not unduly complicated. For a 1-inch diameter full round disk, W_u is approximately 0.05 to 0.06.

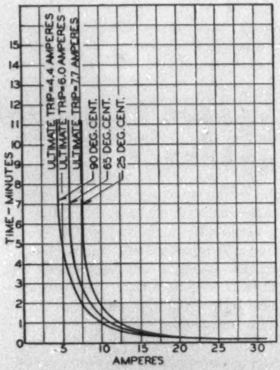

Figure 3. Time-current curves for typical disk-type thermostat at different ambients

Characteristics of Disk-Type Thermostats When Applied to a Motor

The next step is to extend and apply this basic theory to the application of inherent-overheating protection of fractional horsepower motors. Fundamentally, to realize true inherent-overheating protection, the temperature of the thermal disk should at all times follow that of the motor winding; thus the motor winding would always be protected to a definite temperature, regardless of conditions of line voltage, motor load, ambient, or ventilation. If it were possible to make the device infinitesimally small, so that it could be affixed directly to the stator copper beneath the wire insulation, ideal protection could be achieved. Since the thermostat is too large to be embedded in the windings it has to be located elsewhere. A common location is in the end shield as in Figure 7, where it is in as close a heat-receiving relationship to the stator windings as possible. If there were no auxiliary heater, the disk would tend to follow the temperature of the end shield fairly closely. However, the windings almost invariably get hotter than the end shield, by an amount that varies primarily with the current.

For purposes of analysis, it is most convenient to split the total temperature of a motor winding into three components, the sum of which gives the total temperature as follows:

1. Ambient temperature of motor.
2. Temperature rise of end shield above ambient.
3. Temperature rise of windings above end shield.

Now, factor (1) plus factor (2) equals the actual temperature of the end shield, which is the ambient temperature of the thermostat. The temperature of the end shield may be a function of many factors, including ambient temperature in which the motor operates, total losses of the motor (these are affected by voltage, frequency, load, bearing losses, and motor temperature), rpm of the motor, efficiency of the ventilating system, and so forth. Regardless of the number of factors affecting the temperature of the end shield, the thermostat assumes substantially that same temperature thus taking into account all conditions affecting the actual temperature of the end shield. If it were only the end shield temperatures that were significant, it would be sufficient to provide a thermostat responsive only to temperature and not affected by motor current; however, the winding temperature is the significant factor in motor protection, and since the windings get hotter than the end shield, the thermostat is provided with an auxiliary heater which heats the disk and makes the thermostat responsive both to temperature and to current. The problem of proper thermostat selection evolves itself into one of determining which combination of thermostat design features will allow the temperature rise of the disk above the end shield to follow the rise of the motor winding above the end shield.

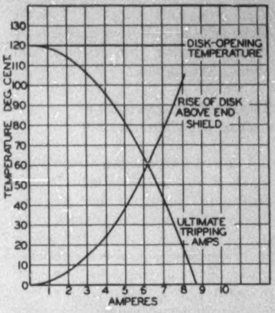

Figure 4. Typical curve of ultimate tripping characteristics for disk-type thermostat

Equation 1 shows that the rise of the disk above the end shield is proportional to the square of the current. With this relationship established, it is necessary to determine the relationship between the winding temperature and the end-shield temperature. In a normal motor, the temperature rise of the end extensions above the end shield is fairly nearly proportional to stator copper loss which in turn, is directly proportional to the square of the stator current. This fact is substantiated by the test data plotted in Figure 8. Here motor currents for various rises of the winding above the end shield are plotted on full logarithmic paper with the resultant curves being straight lines with a slope of two, indicating a square law proportionality.

The equation for the curve of Figure 8 is, by inspection,

$$T_w - T_a = K_m I^2 \tag{5}$$

Where

T_w = winding temperature
K_m = proportionality constant

Rewriting equation 1 to express rise of disk above ambient

$$T_d - T_a = K_t I_u^2 \tag{6}$$

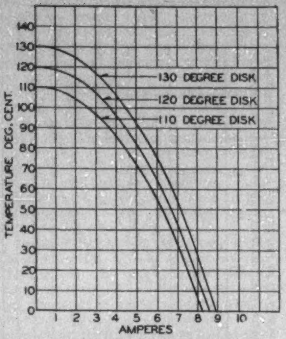

Figure 5. Effect of disk-opening temperature upon ultimate tripping characteristics

Now, since the motor and thermostat are connected in series, $I_u = I$, and the T_a in both equations are the same, it follows by comparing equations 5 and 6 that if

$$K_m = K_t \tag{7}$$

then $T_d = T_w$ for all values of I. That is, the disk temperature is the same as the winding temperature at all loads. All that remains, then, is to set the disk to open at the desired maximum winding temperature.

In other words, the steps in selecting the right thermostat for ideal protection are:

1. Determine K_m by a test on the motor.
2. Select a thermostat having a K_t equal to the tested value of K_m.

(Note: $K_t = (T_d - T_a)/I_u^2$).

3. Use a thermostat with a disk-opening temperature equal to the maximum desired temperature of the winding.

Application of Thermostats to a Line of Motors

If thermostats are applied to a line of motors, using equation 7 it would be necessary to take a test on each motor to determine the value of K_m. This procedure can be simplified by resolving K_m into two components. Let W_m equal total watts copper loss in the main winding per degree rise of winding temperature above end-shield temperature. Let r_1 = resistance of the main winding. Then, equation 5 can be rewritten

$$T_w - T_a = (r_1/W_m)I^2 \tag{8}$$

Now, in contrast with K_m, W_m will remain constant for a number of windings of varying resistance; it is dependent primarily upon the physical size of the motor, with which it can be correlated. Strictly speaking, the hot value of r_1 should be used, but the authors have found it more convenient to use the 25 degrees centigrade value of r_1 and making a slight compensating adjustment in W_m. For further simplification, the effect of ventilation efficiency and motor speed can be neglected by basing the value of W_m on an enclosed motor. Experience has shown that thermostats applied to open motors based upon constants for enclosed motors do not penalize seriously their overload capacity.

For ideal protection, that is, for the temperature of the disk to follow the temperature of the winding at all currents, it is necessary that

$$r_1/W_m = K_t = (T_d - T_a)/I_u^2 \tag{9}$$

When equation 9 is satisfied, the temperature of the disk follows the winding at all currents and ideal protection is obtained. Since the disk always opens at the same temperature, the winding is always protected to the same total temperature. This allows the motor to have appreciably more overload capacity when operating in a low ambient temperature without sacrificing protection in high ambients.

While equation 9 expresses the conditions for ideal protection, practical use of it in this particular form is not quite so easy because values of K_t are not ordinarily published; however, the disk-opening temperatures and ultimate tripping currents at different ambients are usually available. Equation 9 takes on a more usable form if we solve it for I_u, obtaining

$$I_u = \sqrt{(T_d - T_a)W_m/r_1} \tag{10}$$

Then, if we desire to protect the windings to a total temperature of 120 degrees centigrade, the disk-opening temperature, T_d, must also be made 120 degrees centigrade.

Tables for the ultimate tripping current at 90 degrees centigrade are available for 120 degrees centigrade thermostats. For this special case, equation 10 reduces to

$$I_{u90} = \sqrt{30W_m/r_1} \tag{11}$$

where I_{u90} = ultimate tripping amperes at 90 degrees centigrade.

If a thermostat can be found which has a disk-opening temperature of 120 degrees centigrade with an ultimate tripping current at 90 degrees centigrade as given by equation 11, ideal protection is obtained: that is, the thermostat will trip at a winding temperature of 120 degrees centigrade regardless of the load, ambient, or other condition. If the disk-opening temperature varies from 120 degrees centigrade, the ultimate winding temperature will vary by the same number of degrees. If the chosen thermostat has an ultimate tripping current higher than that given by the formula value, the winding temperature will be higher than 120 degrees centigrade. If the chosen thermostat has an ultimate tripping current lower than the formula value, the winding temperature will be limited to less than 120 degrees centigrade.

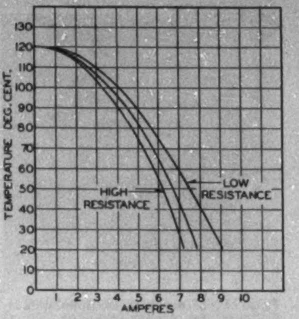

Figure 6. Effect of thermostat resistance upon ultimate tripping characteristics of disk-type thermostat

Some Practical Considerations

What effect do variations in thermostat characteristics have upon protection obtained? That is a question frequently asked. One of the biggest variations in production runs of thermostats is in the disk opening temperature which may vary as much as ± 5 degrees centigrade. Generally speaking, this will cause a variation in winding temperature of ± 5 degrees centigrade, that is, a variation of the same number of degrees as the disk opening temperature; the reasons for this statement are illustrated in Figure 5 and discussed earlier in this paper. Also, in applying thermostats by equation 10 allowance must be made for slight variations in W_m in different motors, and for variations in ultimate tripping current of the thermostats from the published values.

The authors recommend actual verification tests for active designs, but the formula value is usually close enough for low-activity designs. In verifying thermostat applications, the final tripping temperature of the winding should be approached slowly by gradual increases in

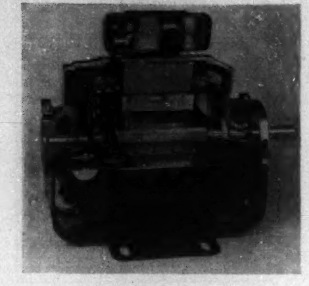

Figure 7. Section view of motor with inherent-overheating protection

Note location of thermostat in upper quadrant of front end shield

motor load allowing the temperature to stabilize between each load point. This type of load gives the highest winding temperature at thermostat trip and represents the worst possible loading condition. This fact is to be expected as the thermostat disk reaches its ultimate temperature more quickly than does the winding since the thermal capacity of the thermostat is smaller than that of the winding. Obviously if the winding and thermostat heater are so matched that ultimately the disk and winding reach the same temperature, the disk will always reach its ultimate temperature before the windings do. The significant conclusion is, that if the thermostat affords protection against a slowly increasing load, it tends to over-protect slightly in severe overloads; that is, in overloads so severe as to cause tripping of the thermostat in a relatively short time.

Summary and Conclusions

1. Inherent-overheating protection, utilizing disk-type thermostats, has proved itself over a period of 19 years. Millions of the devices are in service and their popularity is steadily increasing.

2. Current-operated devices, as distinguished from inherent-overheating devices, limit the current and temperature rise. On the other hand, a true inherent-overheating device limits the total temperature, not the rise, to a constant value.

3. A formula for the ultimate tripping current of a disk-type thermostat, in terms of its fundamental constants, has been derived, equation 4.

4. In deriving equations for the proper application of thermostats for inherent-overheating protection, the end-shield temperature, at the thermostat location, was used as a common reference point because:

a. It is the ambient of the thermostat.

b. It is closely related to the winding temperature.

c. It is less than the winding temperature by an amount proportional to the stator copper loss.

5. For ideal protection, the temperature of the disk should be made to follow the temperature of the winding at all currents. This is accomplished by the use of an auxiliary heater so chosen that the rise of the disk above the end shield is the same as the rise of the winding above the end shield. Since both of these temperature rises are proportional to the square of the current, the disk temperature can be made to follow the winding temperature at all load currents.

6. It follows logically from the foregoing that the disk-opening temperature should be made the same as the desired maximum winding temperature. On this basis, equation 10 has been derived for the ultimate tripping current of a thermostat to give this ideal protection.

7. A significant point brought out is that variations in the disk-opening temperature result in variations of the same number of degrees in the winding temperature.

8. All the considerations in this paper are based upon running overload conditions. Locked-rotor considerations often affect the selection of a thermostat, however, a full discussion of these is beyond the scope of this paper.

Discussion

S. M. De Puy (General Electric Company, Schenectady, N. Y.): The authors have presented a simple and easily understood procedure for the selection of a running overload motor protector.

It should be pointed out that the procedure outlined for selecting a protector is based solely on limiting the temperature of the main winding during running overload. However, a number of factors equally as important as the running overload trip setting may influence the selection of the protector. This is particularly true in the case of a single-phase motor designed for automatic operation which may cycle with locked rotor. The omission of locked rotor protection from this discussion could lead one to believe that locked rotor overheating presents only a minor problem in the application of motors. Yet it is a fact that by far the greatest number of failures from burnout occur in the start winding.

The location, as well as the selection, of a protector has a pronounced effect on its ability to protect the start winding under locked rotor conditions. Veinott and Schaefer have indicated that the protector ambient should be "closely related to the winding temperature." If this relationship could be maintained equally well for running and locked rotor overload, a high degree of protection would result. Unfortunately, this is not always the case. Because of localized heating, high rate of rise, particularly in the start winding, and absence of air circulation, the temperature difference between winding hotspot and protector ambient may be much greater during locked rotor operation than during running overload. Also the protector heater input required becomes less as the protector ambient is made to approach winding temperature under running conditions. Consequently, less power is available to heat the protector element for rapid tripping under locked rotor conditions.

In order to provide satisfactory locked rotor protection, as well as protection for running overload, the protector ambient temperature should be lower than the winding temperature under ultimate tripping conditions by an amount sufficient to insure ample watts for tripping under locked rotor conditions. Fortunately, in many cases a protector, mounted in the motor end shield, will satisfy this requirement.

R. E. Seely (General Electric Company, Fort Wayne, Ind.): In general, I am favorably impressed with Veinott and Schaefer's theory of motor protection and feel that their work is an important step in providing an accurate method for applying motor protection thermostats. The great English physicist Lord Kelvin once said that you know little about a subject until you can measure it. The theory and equations as developed by Veinott and Schaefer enable an investigator to measure and express his results quantitatively. There are, however, a number of comments and suggestions which I would like to make concerning their paper.

The first suggestion which I would like to make is that the authors could perhaps have clarified their presentation if they had utilized a simple electrical equivalent circuit to represent the thermal conditions of a protected motor. In such equivalent circuits, heat flow in terms of watts is analogous to electric current; temperature is analogous to voltage; and thermal resistance is analogous to electrical resistance and can be expressed in terms of degrees centigrade per watt.

The simplest equivalent circuit would consist of three resistances arranged in the shape of a T. The resistance to the left of the vertical resistance would represent the thermal resistance between the stator windings and the end shield. The resistance to the right of the vertical resistance represents the thermal resistance between the disk of the thermostat and the end shield. The vertical resistance represents the thermal resistance between the end shield and the room ambient. The "thermal potential" or temperature of the winding, the disk, the end shield, and the room are T_w, T_d, T_a, and T_r. This means that there is a "thermal potential difference" or temperature difference of $T_w = T_a$ across the thermal resistance between the stator windings and the end shield which results from the flow of I^2R_1 watts through this resistance. It is apparent that the value of the thermal resistance and the end shield is equal to $1/W_m$. This means that the constant, W_m, as proposed by the authors, is in reality the thermal conductance between the stator windings and the end shield. You will note that W_m has the proper dimensions of watts per degree centigrade to indicate thermal conductance. In the same manner as we indicate the voltage drop across an electrical resistance as $E=IR$, we can say that $T_w-T_a=(I^2R_1)1/W_m$ which you will recognize as being the same as equation 8 in Veinott's and Schaefer's paper.

Similarly W_u is the thermal conductance from the disk to the end shield. Equating temperature difference to heat flow multiplied by the thermal resistance we obtain $T_d-T_a=(I^2r_t)1/W_u$ which you will recognize as being the same as equation 3 in the authors' paper.

Apparently, Veinott and Schaefer overlooked the highly desirable procedure of combining these two equations by eliminating T_a between them to obtain the following general equation

$$r_t=R_1(W_u/W_m)-W_u/I^2_c(T_w-T_d)$$

It will be noted that if $T_w=T_d$, the last term of this equation which involves I becomes zero and the equation is reduced to

$$r_t=(W_u/W_m)R_1 \text{ or letting } q=(W_u/W_m)$$

we get $r_t=qR_1$. (It might also be mentioned that this equation could have been derived very easily from Veinott's and Schaefer's equation 9). The fact that the last term of the general equation is reduced to zero when $T_w=T_d$ is in agreement with Veinott's and Schaefer's conclusion that if a thermostat is so selected to give $T_w=T_d$, then ideal protection, unaffected by current, is obtained. The reduced equation

$$r_t=qR_1$$

also indicates the direct relationship between the thermostat resistance and the stator winding resistance which results when ideal protection is obtained. This direct relationship between overload resistance and winding resistance has long been recognized. By using this equation it is possible to calculate the resistance of the thermostat which will give ideal protection once the thermal conductances W_u and W_m or their ratio q have been evaluated for a given line of thermostats and for a given line of motors.

In their paper Veinott and Schaefer have not outlined any test procedure whereby W_m and W_u can be evaluated. To evaluate W_m, I would propose that representative test motors be loaded until the winding temperature T_w is equal to the trip temperature of the thermostat T_d as obtained by heating the thermostat in an oil bath. For this test the thermostat would not carry current and T_a would be measured by means of a thermocouple on the disk of the thermostat. In this connection it has been our experience that T_a as measured in this manner is not the temperature of the end shield, but more nearly the temperature of the motor air. The thermal conductance W_m would be calculated from the formula $W_m=I^2R_1/(T_w-T_a)$ which is derived from Veinott's and Schaefer's equation 8.

Inasmuch as it has been our experience that W_u is somewhat affected by how the thermostat is mounted in a motor and upon the degree of motor ventilation as is W_m, I would propose that W_u be evaluated as follows. Hold the motor winding temperature constant and equal to T_d such that T_a can be assumed to remain constant and equal to its value as measured in determining W_m. Pass a very slowly increasing current I_u from a separate source through the thermostat until it trips. Calculate the thermal conductance W_u by using the formula

$$W_u=I_u^2r_t/(T_d-T_a)$$

which is derived from Veinott's and Schaefer's equation 3. Thermal conductance test made on a number of our fractional horsepower motors in this manner give values of W_m on the order of 1–5 watts per degree centigrade, of W_u on the order of 0.04–0.1 watts per degree centigrade, and of ratio q on the order of 0.012–0.04.

Our experience indicates this method is as accurate as any previous method for selecting motor protection thermostats and that, as pointed out by the authors, verification test of the actual application is still recommended.

It seems probable that Veinott's and Schaefer's method of selecting thermostats is capable of further refinement and of greater accuracy if further investigated in terms of a more exact electrical equivalent circuit for the thermal conditions of a motor.

L. C. Packer (Westinghouse Electric Corporation, Springfield, Mass.): The authors are to be complimented for their very fine paper which presents a problem of interest to all motor designers.

I would like to ask the authors if the constants as derived for their formulas would be adaptable to such special applications as hermetically sealed refrigerator motors. These are very special problems because of the differences in design which affect the gradient between the motor winding and the thermostat. It would be expected that such design variations as vertical versus horizontal motors, or internally spring-mounted as compared with non-internally spring-mounted compressors, or gas, oil, or air cooling would all affect the design of the thermostats and their constants.

In the usual hermetically-sealed compressor with Freon F-12 oil and with cellulose insulation in the motor excessive temperatures will greatly affect the life of the insulation and mechanical parts and will shorten their life to below normal, by first breaking down the insulation into moisture which in turn combines with the Freon to form hydrochloric acid. This acid even in small parts breaks down the oil. This in turn breaks down the insulation at a faster rate than the excessive temperature. Burned out motors, etched valves, and coated pistons and cylinders are the ultimate result of excessive temperatures at overloads, light loads, where gas cooling is used, and in some cases, cycling between drop out and pickup of the relay or under locked conditions.

Burned out starting windings is without doubt the cause of most of the failures of split-phase motors. The temperature of the starting winding will in most cases continue to rise above safe operating temperatures under locked and cycling load conditions with the starting winding in the circuit.

Again I want to compliment the authors

for their fine contribution and would suggest that they expand their methods to cover the special problems found in hermetic units, and also consider the problem of protecting the starting winding. It is very important that the manufacturers of thermostat protection also consider this problem.

C. G. Veinott: DePuy's kind remarks about our paper are appreciated. He is entirely correct in his comment that a number of other factors are equally as important as the running overload trip setting in the selection of a thermostat for inherent protection of a motor. We felt that the subject of locked-rotor protection was too important and too involved to be treated in this paper, if we were to cover running overload protection adequately. Hence the title of the paper indicated that the subject matter was confined to running overload protection. DePuy has not overstated the importance of locked-rotor protection as a factor in the selection of the thermostat. Many times an application, determined solely on the basis of running overload, has to be changed when locked-rotor conditions are covered. However, after a new selection is made, based on adequate locked-rotor protection, it is then necessary to check the correctness of this new application with respect to running overload protection.

During the first few cycles of thermostat operation with rotor locked, the thermostat functions virtually like a current-operated device, and it trips before any appreciable amount of the heat from the windings reaches the thermostat location; hence a definite heater effect is required. In general, we are in full accord with the ideas expressed by DePuy.

Seely's discussion is also very much appreciated. His analogy is very interesting and may help some to grasp the theory we presented in our paper. We suggest he complete his analogy by explaining how the two branches of the T are supplied. Since he took the resistance to the left as representing the thermal resistance between the windings and the end shield, he would have to feed a current into that branch proportional to the I^2r losses in the winding; likewise, into the resistance to the right he would have to feed a current proportional to the I^2r losses in the thermostat. A hydraulic analogy could be made the same way and would serve the purpose equally as well. We, too, think of W_u as the thermal conductance of the disk to end shield, and of W_m as the thermal conductance of the windings to the end shield.

Seely's approach of simplifying our equation 9, showing the thermostat resistance to be directly proportional to the resistance of the main winding was extremely interesting, for that is the first approach we developed to this problem years ago. In fact, we dropped this method with considerable reluctance because it appeared so beautifully simple. The catch is that the ratio q is not a constant, as pointed out by Seely himself; unfortunately, it is a function of the thermostat selected. Theoretically, it is impossible to use this approach because it is necessary to know what thermostat is to be used before a selection can be made, a rather anomalous condition. This tends to make this method somewhat of a cut-and-try method. We get around this difficulty by expressing the desired thermostat performance in terms of its ultimate tripping current, as in our equation 11, which is a very simple equation. The right-hand member of this equation contains no function of the thermostat design or characteristics as does Seely's "q".

Seely raises the question of testing for W_u and W_m. We find that these can be determined satisfactorily by measuring the actual opening temperature of the disk in an oil bath, and then taking an "ultimate tripping test" of the thermally-protected motor. This is done by applying an overload to the motor and allowing all the temperatures to level; the input current is increased by a small increment by increasing the load on the motor and the temperatures again allowed to level; this is continued until the thermostat finally trips. The measured values of current, winding temperature, and end-shield temperature at this point yield directly the values of K_t and K_m; these divided respectively into the thermostat resistance and winding resistance give the values of W_u and W_m. The value of W_u so obtained differs slightly from the value obtained by block test, a correction which has to be taken into account in applying the thermostat.

In reply to Packer's discussion, our method should apply to the application of thermostats to hermetically-sealed refrigerators in those cases where the design of the unit is such that W_m is essentially constant over the operating range. This would be approximately true if the stator laminations are pressed directly into the shell, if the shell receives substantially all of its heat from the motor and not from the compressor or refrigerant, and if the thermostat is mounted directly on the shell. Unfortunately all of these conditions are probably never obtained in a practical refrigeration unit. The applicability of the theory outlined in the paper is directly proportional to the closeness with which the foregoing conditions are realized. In a spring-mounted unit, where all of the motor heat has to be transmitted out through the refrigerant, the ideal conditions outlined are so far from being realized that the thermostat functions, to all intents and purposes, virtually like an external current-operated device and the theory outlined in the paper is probably of very little value.

The Field Fluxes of the Shaded-Pole Motor

E. E. KIMBERLY
MEMBER AIEE

THE pole-shading method of producing starting torque in single-phase a-c motors has been known so long that as early as 1895 at least one improvement patent was allowed.[1] While this type of motor is simplest of all to make, almost nothing has been published to clarify and catalog its field fluxes that make it so difficult to design.

In its simplest form the motor has two, or multiples thereof, salient poles every one of which has a portion of its airgap end surrounded by a short-circuited conductor of one or more turns similar to that shown in Figure 1. In the popular explanation of shading action, the total pole flux Φ is separated into two components of unshaded flux, Φ_u, and shaded flux Φ_s. Because of the inductance of the shading coil, Φ_s is caused to lag Φ_u in time phase α and thus produce a simulated rotating or gliding field of flux moving around the airgap from unshaded to shaded section of the pole. Inasmuch as Φ_u and Φ_s are unequal and their space and time angles (especially the time angle α) are less than 90 degrees, the rotating field is imperfect in that there is also a field moving in the backward direction. Assuming the space angle between Φ_u and Φ_s to be 90 degrees the magnitudes of the forward and backward rotating fundamental fields then may be calculated by 2-phase symmetrical component analysis. Because of over-simplification, this method proves to be only a scientific method of getting the wrong answer in calculating the performance of this type of motor.

At least as early as 1921 it was discovered that an improvement in performance could be achieved by encouraging a part of Φ_s to bypass the rotor through pole extensions (interleaving) from the shaded portion of one pole to the unshaded portion of the adjacent pole.[2] The fact was accepted and a questionable theory was offered. In 1923 the pole extensions idea was extended to include a complete path or bridge of iron from pole to pole around the rotor with only a butt-joint airgap at the mid-point.[3] In 1926, Chester I. Hall[4] used a modified form of the bridge and showed an understanding of its function. In some motors, the bridges are solid without gap of any kind as in Figure 2.

The Problem

The flux distribution in the airgap both as to space and time is affected by saturation and by simultaneous fluxes in opposite directions in the unshaded portion and in the shaded portion of a pole. The purpose of this experimental work is to determine the magnitude and speed of both fundamental and third harmonic fields in the airgap at standstill, at one-third full speed, and full speed. Other harmonic fields if present do not noticeably affect the performance of the special motor used and so have not been investigated. The results are intended to be qualitative rather than quantitative because of the innumerable variables that depend upon size and mechanical proportion.

The Experimental Motor

No available commercial motor is large enough to permit easy application of exploring coils large enough to operate electrical instruments without amplification and possible distortion. To overcome this inconvenience a large motor of dimensions shown in Figure 3, was built as a scale model (excepting the airgap length) of a core-type commercial fan motor or phonograph record-player motor. All tests were made with constant applied voltage rather than constant total armature leg flux because it was thought that the effect of changing the shading-coil resistance could be shown better in that way, inasmuch as the leakage flux in air is affected by change in the shading coil resistance. In order to emphasize the effect of the third-harmonic field which is sometimes annoying, the shading coil slot was made to open into the rotor bore at one-third of a pole pitch from the rotor horizontal center line or the theoretical pole tip.

The shading coils each were made of seven turns of the number 10 copper wire. The two coils were connected in series and to an external noninductive variable resistor. The data on shading-coil circuit resistance are given, however, on the basis of the equivalent single-turn coil. The apparent flux Φ_{sr} in the airgap facing the shaded portion of the pole was found from a 10-turn exploring coil surrounding that portion of the pole and cemented to it. The flux Φ_{ur}, in the airgap facing the unshaded portion of the pole was found similarly. The apparent flux in the shaded portion of the pole was found from an exploring coil around that portion and located adjacent to the shading coil at its end nearest the rotor. The rotor carried 47 round bars skewed one tooth pitch.

The airgap flux was measured from 18 exploring coils of one turn each, cemented to one pole face. Every coil subtended 10 degrees of arc and the 18 coils were distributed over one pole. In some cases where the flux distribution changed rapidly in space around the airgap, intermediate points were obtained. In drawing graphs of airgap flux density the distribution of flux was assumed to be the same under each pole.

The voltages from the exploring coils

Paper 49-72, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted October 27, 1948; made available for printing December 20, 1948.

E. E. KIMBERLY is in the Robinson Laboratory of the Ohio State University, Columbus, Ohio.

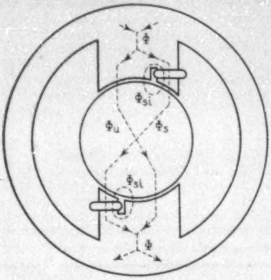

Figure 1 (left). Elemental 2-pole shaded-pole motor showing paths of flux components

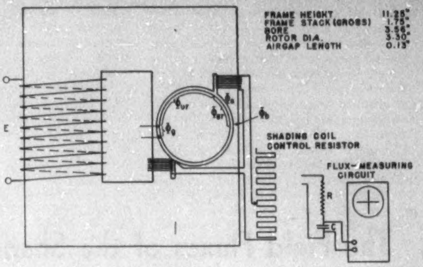

Figure 3 (right). Diagram of the experimental motor and flux measuring circuit

were fed into a reactance-capacitance integrating circuit which gave oscilloscope traces proportional to the net fluxes threading the coils.

The Fundamental Field with Rotor Blocked

To determine the flux distribution around the airgap at any chosen instant of time the magnitude of flux shown by the time trace on the oscilloscope screen at that instant as seen on the repetitive synchronized traces was recorded and plotted against space degrees around the airgap as the measuring circuit was switched to successive airgap exploring coils around the pole face. The same was repeated for instants of time successively later by 30 degrees until data for the six space plots of Figure 4 and Figure 10 were obtained. The fundamental and third-harmonic sinusoidal space component fields have been calculated by Fourier analysis and included in every case.

When the shading coil circuit was open the space waves plotted for 30-degree time intervals showed standing waves of both fundamental and third harmonic flux. Because that case is of slight importance, its graph has not been included, but was drawn to prove the soundness of technique in a simple case.

Figure 2. Core-type shaded-pole motor with bridges between poles showing paths of flux components

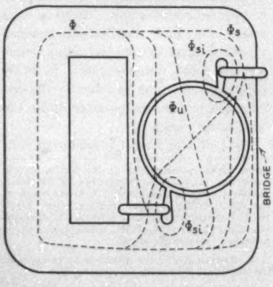

Figure 4 is a series of curves for the case when the shading coil circuit was closed with a little too much resistance (0.00063 ohm) to allow enough fundamental torque to pull the rotor through the cusp caused by the third harmonic field. The shifting of the fundamental field from a position of its maximum density at about the location of the shading coil slot (at 0 arbitrary angle) to advanced positions shown at 30-degree intervals of time is evident from the successive curves. The progress of the fundamental field around the airgap as a function of time is plotted against electrical degrees in the airgap in Figure 5, curve C.

The rotating field is born suddenly with its point of maximum density in the unshaded portion of the pole quite close to the shading coil slot, moves across the shaded portion at almost three times synchronous speed and slows to almost a stop about two-thirds of the way across the following unshaded portion of a succeeding pole. It is then again accelerated and continues its cyclic but erratic course. The field should then be said to sweep from the shaded area of one pole to the unshaded area of the succeeding pole rather than from unshaded to shaded area of the same pole as sometimes has been stated.

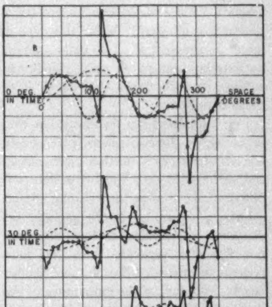
In Figure 5 also is plotted the progress of the fundamental component when the shading coil resistance is adjusted for maximum starting torque (b), and when the resistance is too low for maximum starting torque (a).

Action of the Shading Coil

The component of primary flux which passes through the shading coil acts as the mutual flux of a transformer of which the shading coil is the secondary. The magnetomotive force of the shading coil cur-

Figure 4 (below). Plot of instantaneous flux densities in airgap with rotor blocked and a little too much resistance in the shading coil to produce enough fundamental torque to overpower the third-harmonic torque at about one-third synchronous speed (fundamental)

$R_s = 0.00063$ ohm



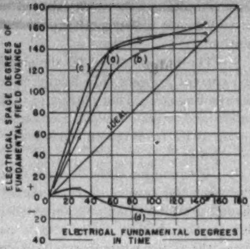


Figure 5. Plot showing space field advance around airgap as a function of time for three values of R_s

(a) Fundamental when $R_s = 0.000107$ ohm
(b) Fundamental when $R_s = 0.000315$ ohm
(c) Fundamental when $R_s = 0.00063$ ohm
(d) Third harmonic when $R_s = 0.000107$ ohm

rent acts on a complicated magnetic circuit in which the path taken by Φ_{st} of Figure 2 is most important. The flux Φ_{st} tends to saturate the shaded section of the pole at the airgap and so to crowd into the bridge that part of the mutual flux which would appear there with no shading coil current flowing. When R_s is decreased the net flux through the shading coil is decreased because of increasing I_s. A plot of this observed relationship is shown in Figures 6 and 7.

Figure 6. Phase relationship and relative magnitudes of fluxes in and around the shaded portion of the pole

t_1 bridge flux is zero. Φ_{sr} is sustained by I_s and is the same as Φ_s

t_2 flux Φ_s is apparently zero but is actually the instantaneous sum of the sustained Φ_{sr} and the reversed Φ_b

t_3 flux Φ_s is actually the same as Φ_b but shows less because there is a sustained Φ_{sr} in opposition

t_4 flux Φ_{sr} has subsided and Φ_b equals Φ_{sr}

However, the shaded portion of the rotor actually has a sustained flux magnitude equal and opposite to the reversed and rising Φ_s component of Φ_{sr}

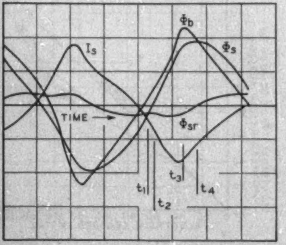

Figure 7 (right). Some effects caused by change in shading coil resistance

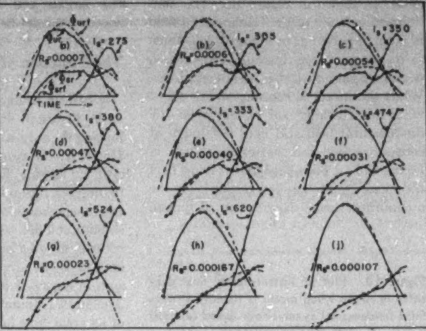
Φ_{sr} is flux entering the rotor opposite the shaded part of the pole. Φ_{ur} is flux entering the rotor opposite the unshaded part of the pole. I_s is the shading coil current. The fundamental components of Φ_{ur} and Φ_{sr} are calculated. Shading coil resistance R_s is varied in steps from 0.0007 to 0.0001 ohm

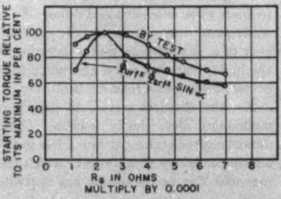


The complex interaction of fluxes Φ_s, Φ_b, and Φ_{sr} is partly shown in Figure 6, for a shading coil resistance which produces maximum starting torque. There is no obvious way to measure either the mutual flux, which is chiefly Φ_b, or Φ_s directly when both exist simultaneously.

In Figure 7, when the shading coil resistance is relatively high the net flux Φ_{sr} is composed largely of mutual flux (the earlier portion of rising Φ_{sr}) which lags behind Φ_{ur} by a small angle, and to a lesser extent by local flux Φ_{st} (the latter portion of rising Φ_{sr}) which is substantially in phase with I_s and lags Φ_{ur} by more than 90 degrees. As the shading coil resistance is decreased, I_s increases and flux Φ_{st} tends to dominate Φ_{sr} both as to magnitude and phase angle by which it lags Φ_{ur}. In Figure 7(J) when R_s is quite low the angle between the fundamental components of Φ_{ur} and Φ_{sr} is greater than 90 degrees. The starting torque produced by the fundamental components Φ_{urf} and Φ_{srf} is a function of $\Phi_{urf} \times \Phi_{srf} \times \sin \alpha$ where α is the time angle between Φ_{urf} and Φ_{srf} if the space angle is 90 degrees. In Figure 8 is shown a plot of starting torque so calculated plotted against R_s and compared with the starting torque as measured by prony brake. These curves show that in a motor as large as the one tested the shading coil resistance readily may be made too small to obtain the maximum starting torque. Under some conditions of shading when the shading coil resistance is too low, it is possible for the harmonic torque (third only investigated) to hinder the starting torque as shown by curve (d), Figure 5, in which the third harmonic flux appears to move backward most of the time.

Figure 8. Starting torque as a function of shading coil resistance

$\Phi_{urf} \times \Phi_{srf} \times \sin \alpha$ plotted from Figure 7 without units to show shape of curve only



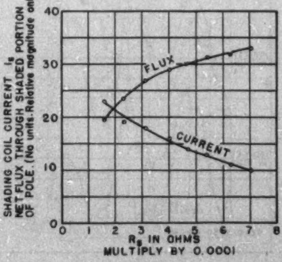
In Figure 9 is plotted the shading coil current and the net shaded section flux as a function of shading coil resistance. This flux curve should theoretically intersect the axes at point 0-0.

The Fundamental Field with Motor Running

When the rotor is permitted to run at about one-third synchronous speed with the shading coil circuit open it is found that the flux density around the airgap

Figure 9. Change in net flux through shaded portion of pole as the shading coil resistance is changed

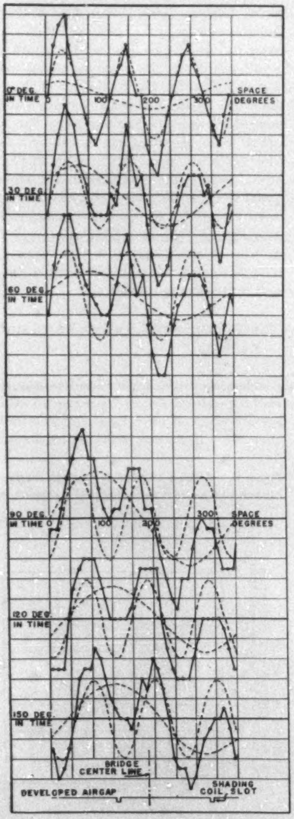
Rotor blocked



varies as shown in Figure 10. The nonuniform velocity of the fundamental field is again apparent as in Figure 4, inasmuch as its progress from instant to instant 30 degrees apart in time is not uniform. When the motor is running at full speed with the shading coil circuit open the fundamental field still does not move at constant speed but varies as shown in Figure 11. The double-revolving-field theory as usually applied accounts for the nonuniform space distribution of flux in the airgap and also for the variable speed of the net field.

Figure 10. Plot of instantaneous flux densities in airgap when motor is running at one-third fundamental synchronous speed (almost) with shading coil open

Six instants of time. Fundamental and third harmonic space components calculated



The Function of the Bridge

When no bridge between poles is used as in Figure 1, Φ_s passes into the rotor lagging Φ_u only a few degrees, α in time. However, the resulting shading coil current I_s, lagging Φ_s somewhat more than 90 degrees sets up its own local flux Φ_{st} which surrounds the slot in which the shading coil lies. The flux Φ_{sr} entering the rotor in an area opposite the shaded pole section is, at any instant, the algebraic sum of a part of Φ_s and the local flux Φ_{st}. The flux Φ_{st} is smaller than Φ_s but because of its great time lag, it causes Φ_{sr} to lag Φ_u more than if Φ_{sr} were composed of Φ_s only.

When the bridge is added it affords a superior path for Φ_s and increases its magnitude. Furthermore the bridge diverts most of Φ_s from its former path through the rotor under the shaded section of the pole. The magnitude of $\bar{I}_s$ and hence Φ_{st} is therefore increased and Φ_{st} becomes a dominating factor in controlling α which should be 90 degrees for maximum starting torque. It appears then that the shading coil side should lie close to the airgap in order to minimize the loss of Φ_{st} by leakage across the unfilled portion of its slot.

The Third-Harmonic Field

Inasmuch as the shading coil slot is located one-third of the way around the pole from the bridge center line, a marked third harmonic field is to be expected. In Figure 4, the third harmonic field is a standing wave and so contributes nothing to the starting torque. With the shading coil resistance adjusted for maximum torque, the third harmonic field moves forward at one-third synchronous speed and contributes to the starting torque. When the shading coil resistance is too low, the third harmonic field moves backward and detracts from the starting torque.

Conclusions

1. The classical rotating field theory without some extension and refinement is inadequate for calculating the performance of a shaded-pole motor because of the highly variable speed and magnitude of the fundamental rotating field.

2. The classical cross-field theory is inadequate also, chiefly because of the almost unpredictable pattern of flux in the airgap caused by conditions in which the magnetic flux in the airgap has opposite sense simultaneously at the shaded portion of a pole and also at the unshaded portion.

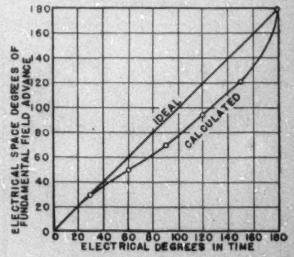
3. The flux produced by the shading coil current appears only locally around the shading coil. That portion of it that enters and leaves the rotor crosses the airgap twice near the embedded side of the shading coil.

4. The function of the bridge is that of diverting the mutual flux through the shaded portion of the pole (magnetizing flux in the shading coil) from a path across the airgap where its small lag angle is detrimental to starting torque. It also serves to increase the magnetizing component of shading coil flux and so to increase the shading coil current and the local flux which it produces with a great time lag behind Φ_{ur}. The magnetizing flux and mutual flux are identical.

5. The starting torque may be impaired by too little resistance in the shading coil. This condition is unlikely to occur in motors of 1/50 horsepower or less, however, because with the same pole section and shading coil proportions a small motor will have less magnetizing flux per ohm of shading coil resistance than will a larger motor. The magnetomotive force responsibilities of the shading coil are determined largely by the airgap length which does not decrease in proportion to the motor size. With less magnetizing flux in a smaller motor, the shading coil resistance should be less in proportion to that flux. It follows then that the shading coil size should not be proportionately reduced as the motor size is reduced.

6. The third harmonic field may cause a serious cusp in the speed-torque curve at about one-third synchronous speed and may even produce a negative torque at start.

Figure 11. Rate of field advance around airgap compared to the ideal when motor is running without load and with shading coil circuit open



Appendix

The use of a resistance-capacitance circuit in connection with an oscilloscope to find the time function of a varying flux Φ by examining the induced voltage e_{rc} produced by it may need some justification.

In the circuit used, if the capacitor current i_c were controlled completely by the resistance R in series with it (effect of capacitor C ignored) then i_c would be a function of e_{rc} which is the exploring coil voltage

$$i_c = Ke_{rc}$$

$$\frac{d\Phi}{dt} = K'e_{rc}$$

$$\int \frac{d\Phi}{dt}\,dt = K'\int e_{rc}\,dt = \frac{K'}{K}\int i_c\,dt$$

$$\Phi = \frac{K'C}{K}\left[\frac{1}{C}\int i_c\,dt\right] = \frac{K'C}{K}e_c$$

Therefore

$$\Phi = K''e_c$$

If then R be made sufficiently large compared to $1/C$, the magnitude and phase angle errors, introduced by a circuit containing $R-jX_c$ instead of R alone, may be held to the same order as those of instrument reading. An analysis of airgap flux distribution with the shading coil open showed the fundamental and third space harmonics to be standing waves both passing through zero at the center line of the stator between poles and for that reason any accumulated errors are apparently negligible. To correct for this error in angle, if desired for accuracy, the flux fundamental or harmonic component under consideration should be set back (retarded in its space position) by the angle whose tangent is $1/\omega CR$.

Electrically Charged Dust in Rooms

G. W. PENNEY
FELLOW AIEE

G. W. HEWITT
MEMBER AIEE

Synopsis: Inefficient electrostatic air cleaners may allow the escape of dust particles carrying electric charges of one sign. Such charged particles, suspended in the air of a room, create a space-charge potential. The resulting voltage gradient drives the charged particles toward the walls. Because of this space-charge effect, the full benefit of air cleaning may not be realized. In addition to the efficiency of the electrostatic air cleaner, other important factors are the concentration of particulate matter in the air, and room size and shape. Ordinarily, the space-charge problem can be solved by high-efficiency cleaning, under particularly severe conditions, such as especially dirty locations and large rooms (such as auditoriums), the use of a neutralizing device may be desirable.

WELL-DESIGNED installations of electrostatic precipitation equipment have given very satisfactory results in keeping buildings clean, but faulty design, installation, or maintenance can cause low efficiency and may result in serious trouble because of the electric charge on any dust escaping from the precipitator. The particles escaping from a precipitator normally carry a charge (usually positive). These charged dust particles suspended in the air in a room, give rise to an electric potential within the room which is a maximum at some central point and decreases toward the walls and other grounded objects. Thus a gradient of potential exists in such a direction as to drive the charged dust toward the walls. The full benefit of the air cleaner is not realized because charged dust near the walls, repelled by other charged dust suspended in the room air, travels more rapidly toward the walls than does uncharged dust. This paper discusses the nature of these effects and the various precautions that should be observed to minimize electrical deposition of dust on walls, so that the full benefit of removing a large percentage of the dust can be realized. This electric charge on dust suspended in the air is referred to in this paper as "space charge."

Demonstration of Space-charge Effects

In an electrostatic precipitator, the air first passes through an ionizer, then through a collector cell. The function of the ionizer is to give each suspended particle an electric charge of a given sign; the function of the collector cell is to remove these charged particles from the air stream by precipitating them upon its plates. If the cleaning efficiency is low because of faulty installation or maintenance, or because of overrating the precipitator, then an increased number of charged dust particles are carried by the air stream into the room.

Electric charges of one sign, carried by dust particles suspended in the air in a room, set up a space charge, resulting in an electrostatic field in the room. Persons in the room cannot sense the space-charge voltage because of the very low energy involved. To measure the resulting voltage, an extremely high-resistance instrument, like an electrostatic voltmeter, is required.

The voltage gradient produced by this charged dust is higher near any parts of the wall that project into the room. Conversely, it is lower on receding parts, such as inside corners or surfaces which are partially shielded by other surfaces. For example, the gradients at such projecting surfaces as those of light fixtures suspended from the ceiling are much higher than those at the wall surfaces. The rate at which dust moves toward surfaces varies directly with the gradient; hence surfaces projecting into the room are soiled rapidly.

These effects were demonstrated using an early precipitator installation from which unsatisfactory performance had been reported. It was found that the installation was such that all of the air passed through the ionizer, but that some ionized air could go through a passage by-passing the collector cells. Also, the precipitator being in a location which was difficult to service, collected dust was allowed to accumulate, almost blocking air flow through the collector cells and forcing about one-half of the air through the leakage path around the collector cells. The resulting efficiency was about 50 per cent, with the half of the dust remaining in the air fully charged. The results of this faulty installation and maintenance were studied in three ways:

1. An electrostatic voltmeter was set up to measure voltages within the room.
2. Specially-devised objects were hung in the room, some being at wall potential and some well-insulated from the walls to show the effect of gradient upon the deposition of dust.
3. The walls and furnishings were examined and pictures taken to show the nature of the dust deposits.

To measure the potential in the room, a disk electrode was mounted from the high-voltage terminal of an electrostatic voltmeter so that the electrode was $4^1/_2$ feet above the voltmeter. This is shown in Figure 1. Such an electrode normally would be very slow to come to the potential of its position in space, and because of some slight leakage, never would fully reach this potential. To increase the rate of response, and to decrease errors, a small amount of radioactive material was placed on the electrode. The material used emitted alpha particles which ionized the air for a distance of a few inches. The resulting air ions near the electrode had a relatively high mobility to move in an electric field, and since there were both positive and

negative ions, the appropriate ion was always present to move to the electrode to bring it to the potential of the space.

Using this instrument, voltage measurements were made in a room supplied with the partially-cleaned air and designated as room *A*. At the same time the "dirtiness" or "blackness" of the air was measured by drawing a measured volume of air through filter paper and measuring the discoloration of the filter paper. The air blackness was evaluated by measuring the change in light transmission through the filter paper caused by the filtered dirt, using a standard illumination and a photocell. The reciprocal of the volume of air required to produce a given discoloration was used as a measure of the blackness.

These tests in room *A* indicated no voltage when the air was clean, while on some smoggy days, the potential in the room was over 2,000 volts. To show that this voltage was not a characteristic of the dirt in the air, duplicate measurements were made in a similar room not equipped with any air-cleaning device and designated as room *B*. In this second room the air was dirtier, but ordinarily there was no measurable potential in the room. The voltage and air blackness measurements for rooms *A* and *B* are given in Table I. Space charge voltage versus air blackness in room *A* is plotted in Figure 2. A rough correlation is evident. An exact correlation would not be expected, since the particle size and other factors vary from day to day.

To show the effect of the voltage gradient at a surface, small probes were made as illustrated in Figure 3. Each probe consisted of a 1/8-inch diameter copper cylinder on which a strip of white paper was spirally wrapped. Portions of this paper surface were covered by three cylindrical paper bands; and the rest was left exposed to the air. Figure 3 shows the construction in three steps. The small bands were used so that at the end of the test, the exposed surface could be compared with the clean unexposed surface.

In each of the two rooms, two probes were suspended, one by a grounded wire, and the other by a fine, waxed-silk thread. The two probes in each room were spaced far enough apart to prevent any appreciable influence upon each other. The grounded wire held its probe at wall potential although suspended in a high-potential region, so the gradient near the probe and rate of blackening was very high, much higher than at the walls of the room. On the other hand, the waxed-silk thread, because of its excellent insulating properties, allowed its probe to attain essentially the potential of the space; the gradient at its surface, therefore, was very low.

Typical probes after a test in room *A* are shown in Figures 4 and 5. In this room which had bad space-charge conditions, the probe at wall potential was badly discolored, while the insulated probe was only slightly discolored. The results of a similar test in room *B* are shown in Figures 6 and 7. In this room with negligible space charge, the grounded and insulated probes show almost the same discoloration.

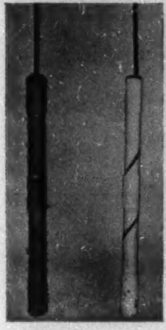
The very slight discoloration of the insulated probe in room *A*, as compared with the grounded probe, might lead one to think that space-charge blackening of the walls could be eliminated by making the walls of highly-insulating material. This, however, is not true, since any air having a net electric charge must have a potential above its enclosing surfaces, so that insulating walls would primarily serve to raise the total potential, with practically no effect on the average discoloration of the walls. It would tend, however, to reduce the nonuniformity of this discoloration.

A typical example of the deposition of dust is shown in Figure 8. The wall consisted of asbestos-board panels with 5/16-inch-thick strips covering the joints between panels. In this picture the heavy deposit of dust on the projecting corners of the strip, and the absence of dust deposits in the protected corners, are very noticeable.

The tests on this faulty installation of electrostatic air cleaning demonstrated three things:

1. Voltages dependent on the amount of particulate matter in the air, can be measured in rooms supplied with air which has passed through an ionizer, but has bypassed the collector cell.

2. If a small surface can be sufficiently well insulated, it can project into the room without being blackened excessively; a



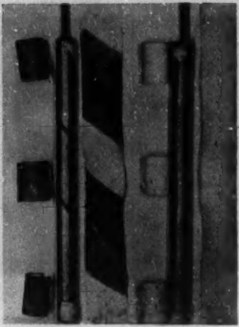


Figure 4 (above). Probes after test in room *A*

Note: In Figures 4, 5, 6, and 7, the grounded probe is shown at the left, and the insulated probe at the right

Figure 7 (above). Paper removed from probes after test in room *B*

similar grounded surface will be blackened very rapidly. This does not mean, however, that making the entire walls of highly-insulating material would eliminate blackening of such walls.

3. Blackening of walls due to space-charge voltages can be recognized by the pattern of the dust deposits, such deposits being heavy on surfaces projecting into the room and lighter on partially-shielded surfaces.

General Analysis

Poisson's equation expresses the relation between potential and position in the room

$$\frac{\partial^2 V}{\partial x^2}+\frac{\partial^2 V}{\partial y^2}+\frac{\partial^2 V}{\partial z^2}=\frac{-4\pi\rho}{k} \tag{1}$$

where

V = potential, statvolts
ρ = volume density of net charge, statcoulombs per cubic centimeter
k = dielectric constant
x, y, z = rectangular coordinates, centimeters

Assuming a uniform net-charge density in air (ρ constant throughout the space, and $k=1$), solutions may be obtained easily for bounding walls of certain simple shapes, such as two infinite parallel planes spaced a finite distance apart, or a spherical shell. The calculation of voltages in actual rooms becomes mathematically involved. It is not the purpose of this paper to treat these difficult cases, but rather to consider simple cases in order to find general trends.

SPACE CHARGE IN A LARGE, LOW ROOM

For the space between two infinite parallel planes, spaced a finite distance (H centimeters) apart in the x direction, the derivatives with respect to y and z are zero and equation 1 reduces to

$$\frac{d^2V}{dx^2}=-4\pi\rho \tag{2}$$

The solution of this is

$$V=-2\pi\rho x^2+C_1x+C_2 \tag{3}$$

where C_1 and C_2 are constants of integration.

Taking the origin at the center of the space, and letting both planes be at zero potential (ground), the constants can be evaluated from the conditions that $V=0$ at $x=H/2$ and at $x=-H/2$.

Then

$$V=(1/2)\pi\rho(H^2-4x^2) \tag{4}$$

and

$$\frac{dV}{dx}=-4\pi\rho x \tag{5}$$

The conditions in a large, unfurnished room with low ceiling are similar to the preceding, except in the regions near the vertical walls.

The maximum potential is in the center of the room, half-way from floor to ceiling, and is approximately

$$V_{\max}=1/2\pi\rho H^2 \tag{6}$$

The maximum voltage gradient is at the center of the floor and of the ceiling, and is approximately

$$\frac{dV}{dx_{\max}}=\pm 2\pi\rho H \tag{7}$$

SPACE CHARGE IN A SPHERICAL SPACE

Poisson's equation, in spherical co-ordinates, for space charge of uniform density in a spherical shell (R centimeters radius) is

$$\frac{2}{r}\frac{dV}{dr}+\frac{d^2V}{dr^2}=-4\pi\rho \tag{8}$$

The solution of this, by integration, is

$$V=-\frac{2}{3}\pi\rho r^2+\frac{C_1}{r}+C_2 \tag{9}$$

The constants may be evaluated by substituting the following boundary conditions:

The voltage gradient is zero at the center ($r=0$) of the spherically-symmetrical space charge, and $V=0$ when $r=R$, the spherical enclosing shell of radius R being at zero potential, that is, ground.

The potential equation is

$$V=2/3\pi\rho(R^2-r^2) \tag{10}$$

The maximum potential is at the center of the sphere ($r=0$)

$$V_{\max}=2/3\pi\rho R^2 \tag{11}$$

The gradient equation is

$$\frac{dV}{dr}=\frac{4}{3}\pi\rho r \tag{12}$$

The maximum voltage gradient is at the wall ($r=R$)

$$\frac{dV}{dr_{\max}}=\frac{4}{3}\pi\rho R \tag{13}$$

AVERAGE GRADIENT OVER BOUNDING SURFACES

The average value of the voltage gradient over the enclosing surface can be calculated very simply. Using the centimeter-gram-second electrostatic system, there are 4 π lines of flux associated with each statcoulomb of charge, and the voltage gradient in statvolts per centimeter is numerically equal to the number of these flux lines per square centimeter in a plane perpendicular to the gradient.

Considering geometrically similar shapes, let:

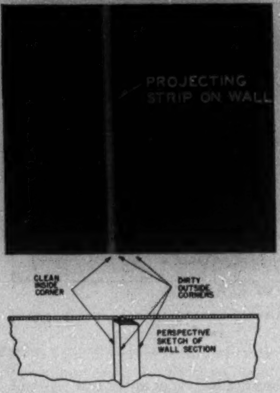

Figure 8. Typical space-charge blackening at a projecting strip on a wall (room *A*)

D = a characteristic linear dimension, centimeters
$v = C_v D^3$ = volume of room, cubic centimeters
$s = C_s D^2$ = area of bounding surfaces, square centimeters
C_v and C_s = factors depending upon room shape
ρ = average net charge density, statcoulombs per cubic centimeter
E_{ave} = average voltage gradient over bounding surfaces, statvolts per centimeter

Then

$$E_{ave} = \frac{4\pi\rho v}{s} = \frac{4\pi\rho C_v D^3}{C_s D^2} = 4\pi\frac{C_v}{C_s}\rho D \qquad (14)$$

For the case of the spherical space charge, the gradient over the whole spherical bounding surface is uniform and therefore equal to the average gradient given by equation 14. Let D = sphere diameter, centimeters. Then $C_v = \pi/6$, and $C_s = \pi$.

Substituting in equation 14

$$E_{ave} = 2/3\pi\rho D \qquad (15)$$

This agrees with equation 13, since $D = 2R$.

For a cube of height D centimeters, $C_v/C_s = 1/6$. Substituting this in equation 14

$$E_{ave} = 2/3\pi\rho D \qquad (16)$$

This shows that the average gradient at the walls would be the same for a cubical room as for a spherical room of equal height. However, the distribution of the gradient over the wall surface would be uniform for the sphere, but nonuniform for the cube. In the latter case, the gradient at the wall would be maximum at the center of the wall and minimum in the corners.

It is evident from equation 14 that for geometrically similar rooms, and a given charge density in the air, the average gradient over the enclosing surfaces is proportional to the size (linear dimension) of the room.

The distribution of this gradient over the bounding surfaces depends upon the configuration of the exposed surfaces. For geometrically similar rooms the distribution of gradient is independent of the size.

The following deductions are indicated by this analysis:

1. Assuming a given amount of dust per unit volume of air, and a given charge per particle, the voltage at the center of the room varies as the square of the dimensions of the room (rooms geometrically similar). The gradient at the wall, which determines the rate at which dust is driven to the wall, is directly proportional to linear dimensions of the room.

2. Assuming the charge to be proportional to the amount of dust per unit volume of air, the voltage gradient at the wall of a given room is proportional also to the concentration of dust in the air. The velocity with which the dust is driven towards the wall is proportional to the gradient, and the rate of precipitation on the wall is proportional to the product of the precipitation velocity times the dirt concentration in the air. In this way, the rate at which a surface becomes dirty is proportional to the square of the amount of dust per unit volume of air.

3. Consider an electrostatic precipitator supplying air to a given room: First, assume that the charge per unit of dirt leaving the precipitator remains constant, as the cleaning efficiency (e) of the precipitator is varied. Then, both the amount of dirt and the amount of charge per unit volume of air in the room varies as $(1-e)$. So the gradient at the walls and the velocity with which dust is being driven toward surfaces also vary as $(1-e)$, and the rate of precipitation upon the surface varies as $(1-e)^2$, that is, the product of precipitation velocity times dirt concentration. Actually, if the efficiency of the precipitator is decreased, either by increasing the air velocity or decreasing the plate length or voltage, the charge per unit of dirt probably will increase rather than remain constant; therefore, the actual rate of blackening of surfaces due to space-charge effects will probably vary more rapidly than $(1-e)^2$. This emphasizes the importance of utilizing the full ability of electrostatic precipitation to yield high efficiency of cleaning.

Engineering Solutions

Obviously, since the space-charge discoloration of surfaces varies more rapidly than the square of the amount of dirt escaping, it is very important to secure an efficient unit, properly installed and maintained. Experience has shown that if this is done, there will be ordinarily no difficulty with space charge in rooms of moderate size. The sealing of the unit so that air cannot by-pass the collector cell, and the distribution of the air so that at no point in the installation does the velocity exceed the rated value, are extremely important factors. Of course it is important to maintain proper voltage, and to clean the units thoroughly and regularly.

In large auditoriums and especially dirty locations, special consideration should be given to space charge because of

**These potentials are believed to have been caused by high-voltage tests which were in progress in the room.

the variation of the effect with size of the room and with dust content of the air. Under particularly severe conditions, a neutralizing device may be desirable. Space-charge difficulties arise from the fact that all particles leaving the precipitator carry charges of one sign (generally positive).

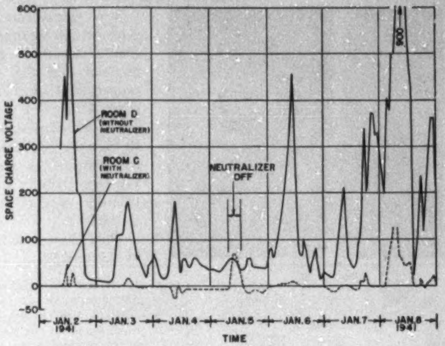

Figure 9. Comparison of space-charge voltages in rooms, with and without a neutralizer

This trouble might be eliminated by reversing the sign of one-half of the dust, or even by charging less than one-half of the dust strongly negative, so that the resultant positive and negative charges are balanced and well mixed.

The requirement of equal positive and negative charges could theoretically be met by operating one-half of the precipitator positive and one-half negative, but this increases the ozone generation (because negative ionizers generate several times as much ozone as positive ionizers) and introduces difficulties from the standpoint of mixing the air.

A method has been devised which uses a single, positive-polarity power pack which supplies both the electrostatic precipitator and a neutralizer which furnishes negative ions.[1] The neutralizer, with its ionizing wires at ground potential and its large electrodes at a high positive potential, takes only a fraction of the discharge air from the precipitator, but charges the particles strongly negative so that the total negative charge carried away approximately equals the total positive charge.

This system has been tested in the laboratory, using the defective precipitator described previously. In addition to the test room *A* this precipitator supplied air to two similar adjacent rooms, *C* and *D*. A neutralizer was installed in the air duct supplying room *C* only. An electrode, equipped with an alpha-particle emitter, was suspended centrally in each room, and connected to a recording electrostatic voltmeter. Records were taken over a period of several months, comparing the space-charge voltages in these two rooms. A plot of these voltages for several successive days is shown in Figure 9.

It was found that the voltage in the room equipped with the neutralizer (room *C*) seldom exceeded 10 per cent of that in the room without the neutralizer (room *D*). In order to demonstrate that this difference in voltage was definitely a result of neutralization, several tests were made with the neutralizer turned off. Under this condition the voltage in room *C* was substantially the same as that in room *D*.

Summary

Dust passing through an electrostatic precipitator carries a charge of one sign which produces a voltage in any room supplied with this air. This voltage tends to drive the charged dust onto walls and other exposed surfaces. The resulting discoloration varies as the first power of the room size (linear dimension), as the second power of the dust content of the air, and as a power of the inefficiency $(1-e)$, which is probably higher than the square, perhaps more nearly the cube.

Space-charge deposition of dust is particularly serious in large rooms, on columns, on hanging light fixtures, and on similar areas exposed to high voltage gradients.

Devices have been developed for neutralizing space charge, but the general experience, in ordinary locations and with moderate size rooms, has been that a unit of high efficiency, properly installed, will not give space-charge difficulties; however, proper installation and maintenance are of extreme importance. Special attention should be given to large rooms, such as auditoriums, and to especially dirty locations.

Heating of Radio-Frequency Cables

WILLIAM W. MACALPINE
MEMBER AIEE

THE THEORY of the heating of radio-frequency cables is developed, based upon the simplest physical and mathematical assumptions, and worked out with the physical picture in mind. The paper is essentially divided into two main parts: the electrical problem and the thermal problem. In the first part there is shown the generation of heat at any point of the conductors and in the dielectric, with its relationship to the standing waves on the cable. The second part treats the diffusion of the heat throughout the cable and its dissipation at the surface. Formulas are developed for computation of the steady-state distribution of temperature along each conductor and in the dielectric. The principal emphasis is upon the application to solid-dielectric coaxial cables. The paper concludes with an example, to illustrate more clearly the use of the theoretical results.

Symbols

Any system of units may be used with the symbols. In the example, unit length is taken to be one centimeter, and unit temperature difference, one degree centigrade. Subscripts 1 and 2 refer to the inner and outer conductors, respectively, while subscript p refers to the dielectric.

Mechanical Symbols

A_1 = cross-sectional area of inner conductor
A_2 = cross-sectional area of outer conductor
r = radius of a point in the dielectric core
r_1 = outside radius of inner conductor
r_2 = inside radius of outer conductor
r_3 = inside radius of jacket
r_s = radius of outside surface of the cable
x = distance along cable, measured toward the generator from a voltage standing-wave minimum

Electrical Symbols

C = capacitance, in farads, of unit length of cable
ϵ = dielectric constant of cable core
E = rms voltage at any location in cable
E_a = rms voltage of forward wave train
E_b = rms voltage of reflected wave train
E_{cr} = rms voltage at crest of standing wave
E_{tr} = rms voltage at trough of standing wave
E_{flat} = rms voltage when standing-wave ratio $=1.0$
e = instantaneous voltage
f = frequency in cycles per second
i = instantaneous value of current
I = rms current at any location in cable
I_p = rms current flowing radially in dielectric core
λ = electrical wave length of cable in centimeters $=3\times10^{10}/f\sqrt{\epsilon}$
P = net power delivered by cable to load
(pf) = power factor of the dielectric
$\psi=4\pi x/\lambda$
R_1 = resistance per unit length of inner conductor at frequency f
R_2 = resistance per unit length of outer conductor at frequency f
(swr) = standing-wave ratio $=E_{cr}/E_{tr}$
$\omega=2\pi f$
Z_0 = surge impedance of cable

Thermal Symbols

$\mathcal{E}$ = effective total emissivity (radiation and convection) of outer conductor acting through the jacket; in calories per second per unit area of outside surface of cable for unit temperature difference of outer conductor above ambient
$\mathcal{E}_s$ = total emissivity of outside surface of cable; in calories per second per unit area of surface for unit temperature difference of the surface above ambient
k_c = heat conductivity of conductor; in calories per second flow across unit cross-sectional area for unit temperature gradient normal to the cross-section
k_p = heat conductivity of dielectric-core material; in same units as k_c
k_s = heat conductivity of jacket material; in same units as k_c
q = rate of heat generation or flow; in calories per second
$q_1=q_1'+q_1''\cos\psi$ = rate of heat generation on inner conductor; in calories per second per unit length
$q_2=q_2'+q_2''\cos\psi$ = rate of heat generation on outer conductor; in calories per second per unit length
$q_p=q_p'-q_p''\cos\psi$ = rate of heat generation in a section of dielectric; in calories per second per unit length of section
u = temperature at any point referred to an arbitrary zero, which is usually the ambient unless otherwise indicated in the context (For subscripts see following paragraph)
u_0 = ambient temperature
U = maximum value of temperature rise when $u=U\cos\psi$ (For subscripts see following paragraph)

In order to specify the location of a temperature, or temperature rise u, and the heat source that causes the rise, the following system of subscripts and primes is used: The first subscript numeral or letter refers to the location of the temperature rise, while the second refers to the source of heat generation causing the rise. When a single prime is used, the rise is due to the part of the heat generation which is uniform over the length of cable in the vicinity of the point in question. A double prime refers to the rise due to the part of the heat generation which is a function of x or ψ. Thus,

u_{12} = rise of inner conductor due to heat generated on outer conductor
u_{21}' = rise of outer conductor due to q_1'
u_{p1}'' = rise of dielectric due to q_1''
U_{11} = maximum temperature of inner conductor due to q_1''

Electrical Problem

Although the losses in a cable cause both attenuation and the generation of heat, in most practical cases the attenuation per 1/2 wave length is so small that for present purposes it can be neglected in writing the voltage and current relations of the transmission line. The line then carries a forward wave travelling toward the load

$$e_a=\sqrt{2}E_a\sin(\omega t+2\pi x/\lambda) \tag{1a}$$

$$i_a=\sqrt{2}I_a\sin(\omega t+2\pi x/\lambda) \tag{1b}$$

and a reflected wave

Paper 49-77, recommended by the AIEE electronics committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 15, 1948; made available for printing December 29, 1948.

William W. Macalpine is with the Federal Telecommunication Laboratories, Inc., Nutley, N. J.

$$e_b = -\sqrt{2}E_b \sin(\omega t - 2\pi x/\lambda) \qquad (1c)$$

$$i_b = \sqrt{2}I_b \sin(\omega t - 2\pi x/\lambda) \qquad (1d)$$

where

$$\left.\begin{aligned} I_a &= E_a/Z_0 \\ I_b &= E_b/Z_0 \end{aligned}\right\} \qquad (1e)$$

and x is the distance along the transmission line measured from a voltage minimum to the point in question, x being positive toward the source. These voltages and currents and their resultants are shown in vector form in Figure 1.

The rms values of the forward and back voltages E_a and E_b are related to the crest and trough voltages of the standing waves along the line by

$$\left.\begin{aligned} E_{cr} &= E_a + E_b \\ E_{tr} &= E_a - E_b \\ E_a &= \frac{1}{2}(E_{cr} + E_{tr}) \\ E_b &= \frac{1}{2}(E_{cr} - E_{tr}) \end{aligned}\right\} \qquad (2)$$

In the generation of heat in the cable, the squares of the resultant rms voltage and current are important. By plane geometry, the diagrams show that

$$E^2 = E_a^2 + E_b^2 - 2E_aE_b \cos\psi \qquad (3a)$$

$$I^2 = I_a^2 + I_b^2 + 2I_aI_b \cos\psi \qquad (3b)$$

where $\psi = 4\pi x/\lambda$.

The power flowing toward the load is E_a^2/Z_0, and that flowing away from the load is E_b^2/Z_0. Then, the net power delivered to the load is

$$P = (E_a^2 - E_b^2)/Z_0 = E_{cr}E_{tr}/Z_0 \qquad (4a)$$

If the line were "flat," then $E_a = E_{flat}$ and $E_b = 0$, so

$$P = E_{flat}^2/Z_0 \qquad (4b)$$

For the same power in equations 4a and 4b there results

$$\left.\begin{aligned} E_{cr} &= E_{flat}\sqrt{(swr)} \\ E_{tr} &= E_{flat}/\sqrt{(swr)} \end{aligned}\right\} \qquad (4c)$$

where E_{cr}/E_{tr} = standing-wave ratio. Whence

$$\left.\begin{aligned} E_a &= (E_{flat}/2)\left[\sqrt{(swr)} + 1/\sqrt{(swr)}\right] \\ E_b &= (E_{flat}/2)\left[\sqrt{(swr)} - 1/\sqrt{(swr)}\right] \end{aligned}\right\} \qquad (4d)$$

and similarly for I_a and I_b.

The power loss in the cable orginates in the conductors and dielectric, these losses being proportional to I^2 and E^2, respectively. The average total power loss over 1/2 wave length is proportional to $E_a^2 + E_b^2$. Consequently, for the same power to be delivered to the load when the cable has standing waves as for a "flat" cable

$$\frac{\textit{Power loss}}{\textit{Loss for ``flat'' cable}} \approx \frac{1}{2}\left[(swr) + \frac{1}{(swr)}\right] \qquad (4e)$$

when the loss is small. The average temperature rise of each conductor, and that of the dielectric, is proportional to the power loss. Thus, the average rise of a cable with standing waves is to that of a "flat" cable as the preceding ratio of power losses. For example, compared to the attenuation and average temperature rise of a "flat" cable, these values must be multiplied by 1.25 for $(swr) = 2.0$, and by 2.125 for $(swr) = 4.0$.

Figure 2 shows the voltage and current waves E and I when $(swr) = 4.0$, and also the squares, E^2 and I^2. Note that whereas $E_{flat}^2 = 1.00$, the maximum E^2 is 4.0, and similarly for I^2. Thus, there are localized power losses of four times the uniformly distributed loss in a "flat" cable.

The rate of generation of heat on the surface of the inner conductor, in calories per second per unit length is

$$q_1 = 0.24I^2R_1 \qquad (5a)$$

and for the inside surface of the outer conductor

$$q_2 = 0.24I^2R_2 \qquad (5b)$$

For computing the heat generated in the dielectric, the cable is considered to be a capacitor with coaxial cylindrical plates of radius r_1 for the outside surface of the inner conductor, and r_2 for the inside surface of the outer conductor. In Figure 3, for a coaxial cylindrical shell or element in the dielectric, the capacitance per unit length is

$$0.0885\epsilon(2\pi r/dr)10^{-12}$$

farads. With a radio frequency current I_p flowing through the dielectric, between inner and outer conductors, the voltage across the cylindrical shell will be

$$dE = \frac{I_p}{\omega}\,\frac{10^{12}}{0.0885\epsilon}\,\frac{dr}{2\pi r}$$

Integrating between the limits r_1 and r

$$E = \frac{I_p}{\omega}\,\frac{\log_e(r_2/r_1)}{2\pi \times 0.0885\epsilon} \times 10^{12} = \frac{I_p}{\omega C}$$

where C is the capacitance in farads per unit length of the coaxial cable. The rate of heat generation in the cylindrical shell in calories per second per unit length is

$$dq_p = 0.24(pf)I_p dE = \frac{0.24(pf)\omega CE^2}{\log_e(r_2/r_1)} \cdot \frac{dr}{r} \qquad (6)$$

this being an incremental or infinitesimal quantity, because the volume of the shell is infinitesimal. If this quantity is integrated between r_1 and r_2, the total heat generated in a unit length of the dielectric is

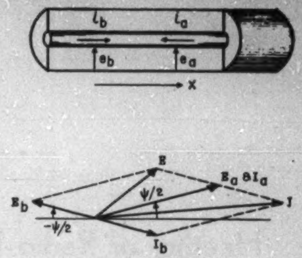

Figure 1. Voltages and currents on transmission line at time $t=0$

Each angle $\psi/2 = 2\pi x/\lambda$ where x is measured toward the generator from a voltage minimum

$$q_p = 0.24(pf)\omega CE^2 \qquad (7)$$

Thermal Problem

The general treatment of the thermal problem has been developed by J. B. J. Fourier (1768–1830),[1] and by numerous others, in works on partial differential equations as applied to such subjects as heat, sound, and electricity. The equations for heat flow are linear, since they involve only constants and the first power of the temperature u, and of its derivatives, and no products of such terms. Therefore, the principal of superposition may be applied. That is, if a source of heat is divided into two parts, or if there are several sources of heat, each source may be treated separately and the resulting temperature rises may then be added.

Heat flow is completely analogous to electric current; temperature difference, to potential difference; and thermal conductivity, to electric conductivity.

All heating of the cable causes temperature change with respect to the ambient temperature but independent of the ambient. This follows from the linear nature of the equations. Throughout the investigation which follows, it will be customary to set the ambient temperature $u_0 = 0$ in the equations and then to add that rise caused by the ambient (the latter is U_0 for some distance in the vicinity of the point in question when the ambient is constant) to the final rise.

In most practical cases, heat may be considered to flow only axially along the inner conductor. Although it flows both axially and radially in the outer conductor, usually the radial temperature gradient is negligibly small. This is because of the small radial dimensions of the conductor, compared to the thermal wave length of the cable (which is half the electrical wave length).

In the dielectric, on the other hand, the principal flow of heat is radial. The axial flow is usually much less than that in the copper, because the thermal conductivity of the dielectric is usually much lower than that of copper. The flow begins to deviate appreciably from the radial direction only when the thickness of the dielectric becomes an appreciable fraction of a thermal wave length. This is not usual in a coaxial cable, however. The axial flow in the dielectric is neglected in the present treatment. Correction terms have been developed in a previous paper,[2] where it is shown that the errors in temperature distribution, caused by neglecting the axial flow, are very small. Generally, the flow may be considered to have circular symmetry about the axis. This will not be quite true if the cable is attached to a surface, so that the dissipation at the outside jacket does not have circular uniformity, or if there is uneven heating of the surface by the sun or other source of radiation. Gas-filled lines may have the circular symmetry, as well as the axial flow, appreciably modified by convection.

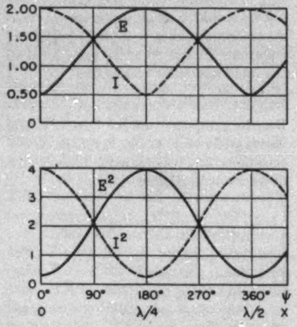

Figure 2. Standing waves, E and I, and their squares, E^2 and I^2, for a cable with standing-wave ratio = 4.0

Arbitrary units are used which would make $E_{flat}=1.00$ and $I_{flat}=1.00$ for the same power delivered to the load. Then $I_a=E_a=1.25$ and $I_b=E_b=0.75$. Average $I^2=I_a^2+I_b^2=2.125$

Some of the steps in the following development have been carried out in greater detail in the previous paper.[2]

Equations of Heat Flow

The conductor of Figure 4 may be solid, tubular, or stranded, but of equivalent thermal conductivity k_c and cross-sectional area A. At a plane normal to the axis, or x co-ordinate, heat flow per second in the direction of increasing x is

$$q=-k_cA\,du/dx \tag{8a}$$

where du/dx is the temperature gradient. At $x+\Delta x$, the temperature gradient is

$$\frac{du}{dx}+\frac{d^2u}{dx^2}\Delta x$$

The heat flow entering the element Δx through the conductor is the sum of that flowing into it across the surfaces x and $x+\Delta x$, or

$$\Delta q=k_cA\,(d^2u/dx^2)\,\Delta x \tag{8b}$$

This axial heat flow into the element, plus the heat generated therein, is equal to the radial flow out of its surface, under steady-state conditions.

In the dielectric of Figure 3, the heat flow at a point with coordinates r, θ, and x, may be resolved into three mutually-perpendicular directions. The net flow along the axial direction into an element $\Delta r\,\Delta\theta\,\Delta x$ is

$$k_pr\,\Delta\theta\,\Delta r\frac{\partial^2u_p}{\partial x^2}\,\Delta x \tag{9}$$

The net radial flow into the element, neglecting small second-order quantities is

$$k_pr\,\Delta\theta\,\Delta x\,\Delta r\left(\frac{\partial^2u_p}{\partial r^2}+\frac{1}{r}\,\frac{\partial u_p}{\partial r}\right) \tag{10}$$

In the third perpendicular direction the flow into the element is

$$k_p\,\Delta r\,\Delta x\frac{1}{r}\,\frac{\partial^2u_p}{\partial\theta^2}\,\Delta\theta \tag{11}$$

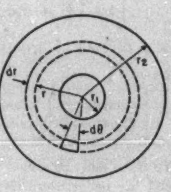

Figure 3. A section of the dielectric

Then total heat flow into the element is

$$\Delta q=k_pr\left(\frac{\partial^2u_p}{\partial r^2}+\frac{1}{r}\,\frac{\partial u_p}{\partial r}+\frac{\partial^2u_p}{\partial x^2}+\frac{1}{r^2}\,\frac{\partial^2u_p}{\partial\theta^2}\right)\times\Delta r\,\Delta x\,\Delta\theta \tag{12}$$

The quantity in parenthesis is the Laplacian, or the divergence of the gradient of u, expressed in cylindrical co-ordinates. In the case of circular symmetry, $\partial^2u_p/\partial\theta^2=0$, and $\Delta\theta=2\pi$. Also, in the event of negligible axial flow, $\partial^2u_p/\partial x^2=0$ for practical purposes, and

$$\Delta q=k_p2\pi r\left(\frac{\partial^2u_p}{\partial r^2}+\frac{1}{r}\,\frac{\partial u_p}{\partial r}\right)\Delta r\,\Delta x \tag{13}$$

This heat flow into the element, plus that generated therein by dielectric heating, is equal to zero in the steady state.

At the boundary between dielectric and inner conductor, the heat flow into the dielectric is, for circular symmetry

$$-k_p2\pi r_1\,\Delta x\frac{\partial u_p}{\partial r}\bigg]_{r_1} \tag{14}$$

and at the outer conductor

$$k_p2\pi r_2\,\Delta x\,\frac{\partial u_p}{\partial r}\bigg]_{r_2} \tag{15}$$

When no heat is generated in the dielectric, and under steady-state conditions with heat assumed to be flowing only radially through the dielectric from inner to outer conductor, the flow per unit axial length has the value, independent of r

$$q=-2\pi k_prdu_p/dr$$

Separating the variables u and r, and integrating between r_1 and any radius r, such as r_2

$$q=\frac{2\pi k_p}{\log_e\,(r/r_1)}\,(u_1-u_p)$$
$$=\frac{2\pi k_p}{\log_e\,(r_2/r_1)}\,(u_1-u_2) \tag{16}$$

It follows that the temperature in the dielectric is a function of r

$$u_p=u_1+(u_2-u_1)\,\frac{\log_e\,(r/r_1)}{\log_e\,(r_2/r_1)} \tag{17}$$

when no heat is generated therein and the flow is radial. This is the same law as that referring to the electric potential as a function of r.

This result can also be derived from equation 13.[2]

Phenomena taking place at the surface of the cable include the dissipation of the heat generated internally, and the heating of the cable by the external surroundings—radiation from the sun and so forth. If the dissipation of heat is the only matter of concern, then, per unit length

$$\Delta q=\mathcal{E}_s2\pi r_s\,\Delta x(u_2-u_0)$$

where $\mathcal{E}_s$ is the surface emissivity, a constant depending on the nature of the surface of the cable and on the medium in which it is immersed. The radius of the surface is r_s, while u_2 is the actual temperature of the outer conductor, and u_0

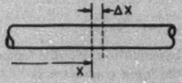

Figure 4. A portion of the conductor

the ambient temperature of the medium. If the cable has a jacket of conductivity k_s, inner radius r_3, outer radius r_s, and $\mathcal{E}_s$ is the surface emissivity of the jacket, then the dissipation per unit length is

$$\frac{2\pi k_s}{\log_e (r_s/r_3)}(u_2-u_3)=2\pi r_s\mathcal{E}_s(u_3-u_0)$$

where u_3 is the actual temperature of the outside of the jacket. This may be written

$$q=2\pi r_s\mathcal{E}(u_2-u_0) \tag{18a}$$

where 3 is now the effective total emissivity of the outer conductor to the surrounding medium, this being found by the relationship

$$\frac{1}{\mathcal{E}}=\frac{r_s}{k_s}\log_e\frac{r_s}{r_3}+\frac{1}{\mathcal{E}_s} \tag{18b}$$

which is analogous to two resistors in series.

Heat Generated on Inner Conductor

According to equations 3b and 5a, the heat generated on a section of the inner conductor of unit length is

$$\begin{aligned} q_1&=0.24R_1(I_a^2+I_b^2+2I_aI_b\cos\psi)\\ &=q_1'+q_1''\cos\psi \end{aligned} \tag{19}$$

which indicates a component uniformly distributed along the conductor, and a sinusoidally varying component. These two components may be treated separately, since the equations of heat flow are linear.

Taking the uniform part of the current-squared distribution, $I_a^2+I_b^2$, it is evident that, for a cable in a uniform medium of constant ambient temperature, or for a part of the cable at some distance from a variation in the medium, the temperature of each conductor will be independent of x, and there will be no heat flow parallel to the axis in either the dielectric or the conductors. The dielectric becomes a simple medium with heat conduction in accordance with equation 16. At the surface, by equation 18a

$$q=2\pi r_s\mathcal{E}(u_2-u_0) \tag{20}$$

per unit length.

The rate q in equation 20 is equal to q_1' in equation 19, being the rate of heat generation per unit length of the inner conductor

$$q_1'=0.24(I_a^2+I_b^2)R_1$$

Therefore, the temperature rise of the outer conductor, above ambient, is

$$u_{21}'=q_1'/2\pi r_s\mathcal{E} \tag{21a}$$

By equation 16, the temperature rise of the inner conductor is

$$u_{11}'=u_{21}'+\frac{q_1'}{2\pi k_p}\log_e\frac{r_2}{r_1} \tag{21b}$$

The variation of temperature with radius in the dielectric is given by equation 17.

The part of equation 19 which is a function of x is

$$q_1''\cos\psi=0.48R_1I_aI_b\cos\psi \tag{22}$$

which is the rate of generation of heat, per unit length. This is equivalent to a sinusoidal heating and cooling of the conductor with a wave length $\lambda/2$, since $\psi=4\pi x/\lambda$. Maximum heating occurs at the current-crest point of the standing waves on the cable, and maximum apparent cooling, relative to the heating caused by q_1', at the current trough.

In the complete cable, two simultaneous equations must be satisfied, one for each conductor. These follow from equations 8b, 16 and 18a, neglecting any axial flow in the dielectric

$$\left\{\begin{aligned} &k_cA_1\frac{d^2u_{11}''}{dx^2}+\frac{2\pi k_p}{\log_e (r_2/r_1)}(u_{21}''-u_{11}'')\\ &\qquad +q_1''\cos\psi=0 &\text{(23a)}\\ &k_cA_2\frac{d^2u_{21}''}{dx^2}+\frac{2\pi k_p}{\log_e (r_2/r_1)}(u_{11}''-u_{21}'')\\ &\qquad -2\pi r_s\mathcal{E}u_{21}''=0 &\text{(23b)} \end{aligned}\right.$$

For the solution, change the variable

$$\frac{d^2u}{dx^2}=\left(\frac{d\psi}{dx}\right)^2\frac{d^2u}{d\psi^2}=\left(\frac{4\pi}{\lambda}\right)^2\frac{d^2u}{d\psi^2} \tag{24}$$

Then

$$u_{21}''=U_{21}\cos\psi=\frac{q_1''\cos\psi}{2\pi r_s\mathcal{E}+\left(\frac{4\pi}{\lambda}\right)^2k_c(A_1+A_2)+\frac{k_cA_1}{2\pi k_p}\left(\frac{4\pi}{\lambda}\right)^2\times\left[k_cA_2\left(\frac{4\pi}{\lambda}\right)^2+2\pi r_s\mathcal{E}\right]\log_e\frac{r_2}{r_1}} \tag{25a}$$

$$u_{11}''=U_{11}\cos\psi \tag{25b}$$

$$U_{11}=U_{21}\left[1+\frac{k_cA_2\left(\frac{4\pi}{\lambda}\right)^2+2\pi r_s\mathcal{E}}{2\pi k_p}\log_e\frac{r_2}{r}\right] \tag{26}$$

To these must be added the ambient, u_0, and the temperature rises, u_{11}' and u_{21}', resulting from the constant component, q_1^1, of the generated heat. The temperature at any point in the dielectric is found by means of equation 17.

Consideration of equations 25a and 26 shows that when the wave length λ is very short, the temperature components U_{11} and U_{21} become negligibly small, as would be expected. When the wave length is very long, on the other hand, the equations reduce to forms similar to equations 21a and 21b. Then the maximum temperature rise, due to heat generated on the inner conductor, is the rise for a "flat" cable multiplied by the standing-wave ratio, and occurs at the voltage standing-wave minimum.

Similar results may be derived from the following equations for the temperature rise due to heat generated on the outer conductor and to heat generated in the dielectric. In the latter case, the maximum temperature rise occurs at the voltage standing-wave maximum.

Heat Generated on Outer Conductor

For heat generated on the outer conductor, the steady-state temperature rise above ambient resulting from the constant component $q_2'=0.24(I_a^2+I_b^2)R_2$ of equations 3b and 5b is the same for both the inner and outer conductors

$$u_{12}'=u_{22}'=q_2'/2\pi r_s\mathcal{E} \tag{27}$$

For the component of the heat that is a function of x or ψ, $q_2''=0.48\,I_aI_b\cos\psi$, the equations are, where axial flow in the dielectric is negligible

$$\left\{\begin{aligned} &k_cA_1\frac{d^2u_{12}''}{dx^2}+\frac{2\pi k_p}{\log_e (r_2/r_1)}(u_{22}''-u_{12}'')=0 &\text{(28a)}\\ &k_cA_2\frac{d^2u_{22}''}{dx^2}+\frac{2\pi k_p}{\log_e (r_2/r_1)}(u_{12}''-u_{22}'')\\ &\qquad -2\pi r_s\mathcal{E}u_{22}''+q_2''\cos\psi=0 &\text{(28b)} \end{aligned}\right.$$

Solving

$$u_{22}''=U_{22}\cos\psi \tag{29a}$$

$$u_{12}''=U_{12}\cos\psi \tag{29b}$$

$$U_{22}=\frac{q_2''}{2\pi r_s\mathcal{E}+k_cA_2\left(\frac{4\pi}{\lambda}\right)^2+1\Big/\left[\frac{\log_e (r_2/r_1)}{2\pi k_p}+\frac{1}{k_cA_1}\left(\frac{\lambda}{4\pi}\right)^2\right]} \tag{30}$$

$$\begin{aligned} U_{12}&=U_{22}\frac{2\pi k_p}{\log_e (r_2/r_1)}\,\frac{1}{k_cA_1\left(\frac{4\pi}{\lambda}\right)^2+\frac{2\pi k_p}{\log_e (r_2/r_1)}}\\ &=\frac{U_{22}}{1+\frac{k_cA_1}{2\pi k_p}\left(\frac{4\pi}{\lambda}\right)^2\log_e\frac{r_2}{r_1}} \end{aligned} \tag{31}$$

Heat Generated in Dielectric

When the heat conductivity of the dielectric is small compared to that of the conductor material, and for usual cross sections of cable, the axial heat flow in the dielectric can be neglected to a first approximation, as was done in the cases treated in preceding paragraphs. Then by equations 3a, 6, 7, and 13, the differential equation for the temperature distribution in the dielectric is

$$r^2\frac{d^2u_p}{dr^2}+r\frac{du_p}{dr}+\frac{q_p}{2\pi k_p\log_e (r_2/r_1)}=0 \tag{32a}$$

where

$$q_p=0.24(pf)\omega C(E_a^2+E_b^2 -2E_aE_b\cos\psi)=q_p'-q_p''\cos\psi \quad (32b)$$

A solution of equation 32a is

$$u_p=a+b\log_e\frac{r}{r_1}-\frac{q_p\left(\log_e\dfrac{r}{r_1}\right)^2}{4\pi k_p\log_e\dfrac{r_2}{r_1}} \quad (33a)$$

The boundary conditions are $u_p=u_1$ at $r=r_1$ and $u_p=u_2$ at $r=r_2$, whence

$$u_p=u_1+\left(\frac{u_2-u_1}{\log_e(r_2/r_1)}+\frac{q_p}{4\pi k_p}\right)\log_e\frac{r}{r_1} -\frac{q_p}{4\pi k_p\log_e(r_2/r_1)}\left(\log_e\frac{r}{r_1}\right)^2 \quad (33b)$$

It is to be noted that equation 33b is general; it includes the temperature distribution resulting from heat generated externally to the dielectric, as well as that generated internally. It reduces to equation 17 when $q_p=0$; and to equation 38 when $q_p''=0$, provided that only the heat generated in the dielectric is considered. This result may be derived also by simple integration.[2]

For the distribution of temperature along the conductors resulting from heat generated in the dielectric, it is noted that, in the steady state, the net heat flow into an element Δx of the conductor is zero. For the inner conductor, by equations 8b and 14; and for the outer conductor by equations 8b, 15 and 18a, letting $u_0=0$

$$k_cA_1\frac{\partial^2u_{1p}}{\partial x^2}+2\pi r_1k_p\frac{\partial u_p}{\partial r}\bigg]_{r_1}=0 \quad (34a)$$

$$k_cA_2\frac{\partial^2u_{2p}}{\partial x^2}-2\pi r_2k_p\frac{\partial u_p}{\partial r}\bigg]_{r_2}-2\pi r_s\mathcal{E}u_{2p}=0 \quad (34b)$$

Differentiating equation 33a or 33b

$$\frac{\partial u_p}{\partial r}=\frac{b}{r}-\frac{q_p}{2\pi rk_p\log_e(r_2/r_1)}\log_e\frac{r}{r_1} \quad (35)$$

which, substituted in equations 34a and 34b, gives

$$k_cA_1\frac{\partial^2u_{1p}}{\partial x^2}+2\pi k_p\frac{u_{2p}-u_{1p}}{\log_e(r_2/r_1)}+\frac{q_p}{2}=0 \quad (36a)$$

$$k_cA_2\frac{\partial^2u_{2p}}{\partial x^2}+2\pi k_p\frac{u_{1p}-u_{2p}}{\log_e(r_2/r_1)}+\frac{q_p}{2}- 2\pi r_s\mathcal{E}u_{2p}=0 \quad (36b)$$

Note that the heat entering the dielectric, the negative of the second plus third terms of equation 36a, plus the heat, q_p, generated therein, is equal to that leaving the dielectric, which is the second plus third terms of equation 36b.

Taking first the constant part q_p' of equation 32b, a reasonable supposition is that u_{1p} and u_{2p} are independent of x, as was the case for the constant part of the heat generated on the conductors. It follows that $\partial u_{1p}/\partial x=0$ and $\partial u_{2p}/\partial x=0$. From equation 34a, or from the fact that conditions are in equilibrium (no heat flow into or out of the inner conductor), it follows that

$$\frac{\partial u_p}{\partial r}\bigg]_{r_1}=0$$

Whence, from equation 36a

$$u_{1p}'=u_{2p}'+\frac{q_p'}{4\pi k_p}\log_e\frac{r_2}{r_1} \quad (37a)$$

and from equations 36a and 36b, or from elementary considerations

$$u_{2p}'=q_p'/2\pi r_s\mathcal{E} \quad (37b)$$

When equation 37a is substituted in equation 33b, it is found that the temperature distribution caused by q_p' acting alone is

$$u_{pp}'=u_{1p}'-\frac{q_p'}{4\pi k_p\log_e(r_2/r_1)}\left(\log_e\frac{r}{r_1}\right)^2 \quad (38)$$

The variable part of q_p, which is $-q_p''\cos\psi$ when substituted in equations 36a and 36b gives equations of a type similar to equations 23a and 23b. The solution is

$$u_{2p}''=U_{2p}\cos\psi \quad (39a)$$

$$u_{1p}''=U_{1p}\cos\psi \quad (39b)$$

The coefficients U_{1p} and U_{2p} are determined by subsituting equations 39a and 39b into equations 36a and 36b

$$-\left[k_cA_1\left(\frac{4\pi}{\lambda}\right)^2+\frac{2\pi k_p}{\log_e(r_2/r_1)}\right]U_{1p} +\frac{2\pi k_p}{\log_e(r_2/r_1)}U_{2p}=\frac{q_p''}{2} \quad (40a)$$

$$\frac{2\pi k_p}{\log_e(r_2/r_1)}U_{1p}-\left[k_cA_2\left(\frac{4\pi}{\lambda}\right)^2 +\frac{2\pi k_p}{\log_e(r_2/r_1)}+2\pi r_s\mathcal{E}\right]U_{2p}=\frac{q_p''}{2} \quad (40b)$$

The simplest means of solving equations 40a and 40b is to substitute the numerical values in the coefficients from the dimensions and constants of the cable. Then solve the resulting linear simultaneous equations for U_{1p} and U_{2p}.

The temperature distribution in the dielectric is given by equation 33b.

Example

As an example of the practical application of the equations developed in this paper, consider a type *RG-19/U* cable delivering 5 kw continuously to a load, the frequency being 100 megacycles per second. Two cases will be considered: *A*—where the cable is "flat," or standing-wave ratio = 1; *B*—where the standing-wave ratio is 2.0.

This cable is made up as follows:

Inner conductor: solid plain copper, 0.250-inch diameter
Cable core: solid polyethylene, 0.910-inch outside diameter
Outer conductor: single-layer braid, 48×9, 30-gauge (Brown and Sharpe) plain copper wires. Maximum (allowable but not necessarily actual) diameter is 0.990 inch
Jacket: synthetic resin, outside diameter 1.120 inches

The specified nominal characteristics are:

Surge impedance = 52 ohms
Capacitance = 29.5 micromicrofarads per foot
Attenuation = 0.68 decibel per 100 feet at 100 megacycles

Then, the various constants of the cable are:

$r_1=0.318$ centimeter
$r_2=1.16$ centimeters
$r_3=1.21$ centimeters (estimated average value)
$r_s=1.42$ centimeters
$A_1=0.317$ square centimeter
$A_2=0.220$ square centimeter
$k_c=1.0$ calorie per second per square centimeter for one degree centigrade per centimeter
$k_p=8\times10^{-4}$ calorie per second per square centimeter for one degree centigrade per centimeter
$k_s=4\times10^{-4}$ calorie per second per square centimeter for one degree centigrade per centimeter (estimated)
$\mathcal{E}_s=3\times10^{-4}$ calorie per second per square centimeter for one degree centigrade temperature difference (estimated: depends upon conditions of installation)

$\epsilon=2.3$ (dielectric constant of core)
$(pf)=4\times10^{-4}$
$C=0.97\times10^{-12}$ farad per centimeter
$Z_0=52$ ohms

From these constants other derived parameters are found:

$\mathcal{E}=2.6\times10^{-4}$ calorie per second per square centimeter for one degree centigrade temperature difference; by equation 18b
$R_1=1.48\times10^{-3}$ ohm per centimeter
$R_2=0.525\times10^{-3}$ ohm per centimeter

The values of R_1 and R_2 are taken to be slightly higher than the ideal theoretical values for 100 megacycles, but, together with the power-factor value listed, when used to calculate the attenuation of the cable, result in the specified value of 0.68 decibel per 100 feet.[1]

For the given frequency, power, and standing-wave ratio, the following quantities are found:

$\lambda=198$ centimeters

A. For the "flat" line, standing-wave ratio = 1:

$E_{flat}=510$ rms volts (4b)
$I_{flat}=9.80$ rms amperes (1e)

$q_1 = 34.1 \times 10^{-3}$ calorie per second per centimeter (5a)

$q_2 = 12.1 \times 10^{-3}$ calorie per second per centimeter (5b)

$q_p = 15.2 \times 10^{-3}$ calorie per second per centimeter (7)

B. For the line with standing-wave ratio = 2.0:

$E_a = 540$ rms volts (4d)

$E_b = 180$ rms volts (4d)

$I_a = 10.4$ rms amperes (1e)

$I_b = 3.46$ rms amperes (1e)

$q_1' = 42.5 \times 10^{-3}$ calorie per second per centimeter (19)

$q_1'' = 25.6 \times 10^{-3}$ calorie per second per centimeter (19)

$q_2' = 15.1 \times 10^{-3}$ calorie per second per centimeter

$q_2'' = 9.1 \times 10^{-3}$ calorie per second per centimeter

$q_p' = 19.0 \times 10^{-3}$ calorie per second per centimeter (32b)

$q_p'' = 11.4 \times 10^{-3}$ calorie per second per centimeter (32b)

Note that

$$q_1'/q_1 = q_2'/q_2 = q_p'/q_p = 1.25 \qquad (4e)$$

For the "flat" cable carrying 5 kw at 100 megacycles, the total heat generated is $q_1 + q_2 + q_p = 61.4 \times 10^{-3}$ calorie per second per centimeter, as tabulated in the preceding paragraph. The specified attenuation of the cable at 100 megacycles is 0.68 decibel per 100 feet, which is equal to 0.223×10^{-3} decibel per centimeter. This attenuation, acting on 5 kw, results in a loss of 0.258 watt per centimeter, or 61.7×10^{-3} calorie per second per centimeter, which checks closely the total heat generated.

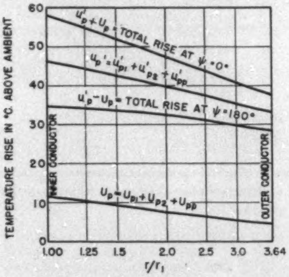

Figure 5. Temperature rise of the dielectric

Computed for a type *RG-19/U* cable carrying 5 kw continuously at 100 megacycles per second, with standing-wave ratio = 2.0. At inner conductor, $u_p' = u_1'$, while at outer conductor, $u_p' = u_2'$. Similarly for U_p and all other quantities with subscript *p*

For use in applying the formulas, certain quantities which occur several times are here evaluated

$\log_e (r_2/r_1) = 1.29$

$2\pi r_s \mathcal{E} = 2.32 \times 10^{-3}$

$2\pi k_p / \log_e (r_2/r_1) = 3.90 \times 10^{-3}$

$4\pi k_p = 10.1 \times 10^{-3}$

$4\pi k_p \log_e (r_2/r_1) = 13.0 \times 10^{-3}$

$(4\pi/\lambda)^2 = 4.05 \times 10^{-3}$

$k_c(A_1 + A_2)(4\pi/\lambda)^2 = 2.18 \times 10^{-3}$

$k_c A_2 (4\pi/\lambda)^2 = 0.89 \times 10^{-3}$

$k_c A_1 (4\pi/\lambda)^2 = 1.28 \times 10^{-3}$

$(k_c A_1 / 2\pi k_p)(4\pi/\lambda)^2 = 0.258$

The principal temperature rises are given in Table I and Figure 5. The data and curves are the result solely of computation from the specified dimensions and construction of the cable, and the published physical characteristics of its component parts. No experimental tests have been made in this connection to confirm the data. Some of the tabulated temperature rises for the 5 kw power value probably exceed the safe limit for this cable.

The column headed "If k_c were 0" gives hypothetical values which, when compared to the "Actual" column, show the effect of axial flow in the conductors in reducing temperature variation along the cable.

The Power Rating of Radio-Frequency Cables

R. C. MILDNER
ASSOCIATE AIEE

THIS paper deals with the limitations to the radio-frequency power which can be transmitted by cable. In the first place the normal electrical losses of the transmission line create heat within the cable. Secondly, excessive electrical stress may have two deleterious effects on the performance of the cable. The increased losses due to discharges may cause local overheating, or the discharges may cause a local deterioration of the insulation, leading to electrical breakdown.

The principles used in calculating the temperature rise are set down. The standard thermal rating of the cable is defined as the power that can be transmitted by the cable into a matched load with a given temperature rise for the steady-state condition. Suitable rating factors to deal with different maximum permissible temperatures and different ambient temperatures are proposed. The influence on the thermal and voltage rating of various operating conditions, such as modulation, standing waves, and load factor is briefly considered.

The principles outlined are applied to obtain the technical ratings of three, interesting ranges of cables and reference is made to the influence of various factors in the design.

The last decade has seen an amazing expansion in the use of high-frequency generators of high and medium powers. Among the applications of such transmitters may be included sound and vision broadcasting, communications systems, radar and navigational aids, medical appliances, and industrial heaters, using induction or dielectric heating effects. In most cases some form of transmission line is required to carry the radio-frequency power from the generator to the antenna, work coil, or operating electrode.

For all except the very highest frequencies, this transmission is by wire. For the highest powers, open-wire feeders have been used because their construction permits relatively wide spacing. This advantage is lost as frequencies of about 100 megacycles per second are approached, and the use of coaxial feeders has other attractive features. For mobile transmitters, flexible cables are almost indispensable and for fixed stations of medium power, cables or built-up coaxial feeders are commonly used.

On economic grounds the size of the cable would be determined by equating the rate of change of the annual charges associated with the cost of the cable to the rate of change of the annual cost of the energy lost in maintaining the required power at the antenna. Sometimes, however, the size of the cable to be used will be determined by technical considerations, namely, its ability to transmit the required power without damage to the cable structure. The power lost in the feeder will raise its temperature and may cause excessive deterioration by chemical or mechanical action due to thermal expansion or softening. The voltages associated with the input power will impose dielectric stresses on the cable insulation, and these may be sufficiently high to cause partial or complete electrical breakdown, with resultant over-heating or deterioration of the insulation. Either of these two processes may be effective according to operating conditions or cable design.

It is therefore important to establish for each cable type the maximum power it can carry safely without either of these effects intervening. These ratings will serve as a guide to the appropriate type to be used in any application.

Sometimes the equipment designer may require a practical test to establish that the feeder is able to carry the required power with a reasonable margin of safety. The results of such practical tests must be analysed to determine in what way the cable performance would be modified by the minor variations in quality which would be permitted by the acceptance specification. A study of the principles on which these ratings are based will indicate the manner in which such an analysis might be made.

Thermal Rating of Cables

In an earlier paper[1] the author considered the thermal rating of radio-frequency cables, more particularly from the standpoint of their use in equipment for the armed services. Specific ratings were proposed for a number of standard Uniradio and Duradio cables commonly used in England. The present section is therefore a development of the principles stated there, adapted to a wider field of application.

A theoretical basis of calculation, supplemented, where necessary by empirical constants, has been used throughout the paper, because it is necessary to state the precise location in the cable of the various sources of heat. The electrical losses, which are the source of heat, are calculated from the components of attenuation due to the inner conductor, the insulation, and the outer conductor. The thermal resistances of the component parts of a cable system are calculated from the dimensions and from the constants of the materials employed.

The methods used to calculate the temperature rise corresponding to a given heat loss are based partially on principles widely used in England to calculate the current rating of power-frequency cables,[2] since the methods used in the United States are not dissimilar and lead to com-

Table I. Field Factors for Stranded Conductors

Number of Strands n	m	Factors k_1	k_2
1	1	1.0	1.0
7	6	0.939	1.408
19	12	0.970	1.397
37	18	0.980	1.395
61	24	0.985	1.394
91	30	0.988	1.394

parable ratings, they may be found acceptable in the present instance. The permissible maximum temperature of operation determines the allowable heat dissipation in terms of the ambient temperature and this dissipation is converted readily into terms of input power.

Practical tests on a limited number of radio-frequency cables[3] have given overall temperature rises substantially in agreement with those predicted by the present treatment. It may therefore be accepted that the theoretical values constitute a reasonable basis for establishing power ratings.

In the equations for attenuation given later and in the theoretical treatment, the attenuation coefficient (α) is expressed in nepers per centimeter, whereas the tabulated values of cable characteristics are given in decibels per 100 feet; the attenuation in decibels per 100 feet is given by $2.65\times10^4\times\alpha$. The thermal coefficients are expressed in centimeter-gram-second and centigrade units. Practical units are used throughout the paper.

THE ATTENUATION COEFFICIENT OF CABLES

The theoretical attenuation of ideal coaxial and balanced lines formed by cylindrical conductors has been covered adequately in published literature. Practical cable constructions often deviate from this ideal form and the formulas given herein follow the classical lines, but include certain empirical factors to cover the effect of such divergences as stranding, braiding, and the use of bimetallic conductors. Considerable data on the attenuation of actual cables over a wide range of frequency have been amassed over the last few years, and the factors proposed here are based on part of that experience. In the normal run of production cables will exhibit a spread of results about the "standard" attenuation determined in this way. For the purpose of assessing the power rating of a given design of cable, a figure 10 per cent higher than the standard attenuation is proposed. This allowance is intended to cover minor variations of construction and of the quality of materials. Where a cable has to satisfy a specification calling for a maximum value of attenuation at the operating frequency, this maximum value should of course be used to estimate the power rating. For general purpose cables, the specified value is not likely to be greatly different from the value given here.

Table II. Calculated Values of Resistance Factor for Tinned Copper Surface

Thickness of Tin: 0.2 mil

Frequency, Megacycles per Second	K_ρ
1	1
5	1
20	1.03
100	1.16
200	1.26
600	1.96
1,500	2.65
3,000	2.92

Following classical theory, the attenuation of a transmission line at high frequencies is given by

$$\alpha=\frac{R}{2}\sqrt{\frac{C}{L}}+\frac{G}{2}\sqrt{\frac{L}{C}}\text{ nepers per centimeter} \quad (1)$$

where R, G, L, and C are the primary coefficients of the line. In this formula the first term is the conductor loss and the second the dielectric loss. For the case of the coaxial line, R is the sum of the resistances of the inner conductor, R_1, and of the outer conductor, R_2. Exact solutions for R_1 and R_2 have been obtained in terms of Bessel functions. Tabulated value of the appropriate function in terms of the parameter $\pi d\sqrt{2\mu f/\rho}$ have been published.[4] For values of this parameter which are greater than 70, the surface resistance of a conductor is given by

$2\pi\sqrt{\rho\mu f}$ ohms

to an accuracy better than 1 per cent. Since this condition obtains, for most practical cables, at frequencies not much greater than a megacycle, this latter value has been adopted in the following equation. In similar fashion, the inductance due to flux in the space between the "go" and "return" conductors is enhanced at low frequencies by the internal inductance of the conductors. This correction also may be neglected at very high frequencies as defined before. With small high-attenuation cables, the characteristic im-

List of Symbols

α_c = attenuation due to conductors, nepers per centimeter
α_{c1} = attenuation due to inner conductor, nepers per centimeter
α_{c2} = attenuation due to outer conductor, nepers per centimeter
α_d = attenuation due to dielectric, nepers per centimeter
α = total attenuation of cable, nepers per centimeter
d = outer diameter of inner conductor, centimeter
D = inner diameter of outer conductor, centimeter
D_s = diameter of outer surface of cable, centimeter
$f=\omega/2\pi$ = frequency, cycles per second
G_a = thermal resistivity of air, degrees centigrade, centimeters per watt
G_c = thermal resistivity of servings, degrees centigrade, centimeters per watt
G_d = thermal resistivity of dielectric, degrees centigrade, centimeters per watt.
G_g = thermal resistivity of ground, degrees centigrade, centimeters per watt
h = semispacing of conductors of balanced cable, centimeters
H_θ = dissipation, in watts per centimeter, corresponding to a temperature rise of θ degrees centigrade at the inner conductor
θ_i = temperature rise of inner conductor, degrees centigrade above ambient
θ_r = temperature rise of outer conductor, degrees centigrade above ambient
θ_s = temperature rise of surface of cable, degrees centigrade above ambient
k = thermal dissipation constant for surface in air
κ = permittivity of dielectric
K_b = ratio of resistance of outer conductor to that of equivalent cylindrical conductor (braiding factor)
K_ρ = proximity factor
K_ρ = ratio of resistance of outer conductor to that of a similar conductor constructed in the same material as inner conductor
K_s = ratio of resistance of stranded conductor to that of equivalent cylindrical conductor (stranding factor)
l = depth of cable axis below ground surface, centimeters
ρ = resistivity of conducting material, ohm-centimeters
ρ_1 = resistivity of inner conductor material, ohm-centimeters
μ = permeability of conducting material, henrys per centimeter
S_a = thermal resistance external to unit length of cable in air, degrees centigrade, centimeters per watt
S_c = thermal resistance of servings for unit length of cable, degrees centigrade, centimeters per watt
S_d = thermal resistance of insulant for unit length of cable, degrees centigrade, centimeters per watt
S_g = thermal resistance external to unit length of cable in ground, degrees centigrade, centimeters per watt
$\tan\delta$ = loss tangent of dielectric
P_0 = mean input power, watts
Z_0 = characteristic impedance of cable, ohms
E = voltage on cable, volts
I = current along cable, amperes

pedance may be complex, and higher than the value at very high frequencies, at frequencies of the order of one megacycle per second. In such cases the formulas given below will be subject to some error.

The constants given in the succeeding sections for the attenuation coefficients relate to atmospheric temperature (20 degrees centigrade). In calculating the thermal rating of cables, an enhanced value of this coefficient must be used to allow for the rise in temperature of the cable.

Since the conductor losses are proportional to the square root of the resistivity, the temperature coefficient of attenuation due to the conductors will be of the order 0.002 per degrees centigrade for most of the materials used in the construction of radio-frequency cables. Since the contribution of loss by the outer conductor is usually considerably smaller than that due to the inner conductor and since the ratings are based on relatively high values of ambient temperature, it has been considered sufficiently accurate to assume that the proportionate increase of loss is the same for the outer conductor as for the inner.

The temperature coefficient of attenuation due to the dielectric depends essentially upon the temperature coefficient of the power factor, which may be positive or negative, as explained in the section on Power Factor of Insulant. Since the attenuation due to the dielectric is based on a maximum value of power factor which is assumed to apply to all frequencies and temperatures, the corresponding temperature coefficient has been assumed to be zero for the purpose of these calculations.

ATTENUATION OF COAXIAL CABLES

At very high frequencies, as defined before, the attenuation is given approximately by the expression

$$\alpha = \frac{2.287\times10^{-7}\sqrt{\kappa\rho_1 f}}{\log_{10} D/k_1 d}\left\{\frac{K_s}{d}+\frac{K_b K_\rho}{D}\right\}+ 1.047\times10^{-10}\sqrt{K}f\tan\delta \quad \text{nepers per centimeter} \qquad (2)$$

The first term represents the attenuation due to the conductors, the two components of this term relating to the inner and outer conductor respectively: the second term gives the attenuation due to the dielectric. The factor k_1 allows for the effect of stranding on the capacitance and inductance of the cable. The factor K_s allows for the effect of the form of the inner conductor on its resistance, K_b allows for the effect of the form of the outer conductor on the resistance and K_ρ allows for the effect of the material of the outer conductor where it differs from that of the inner conductor. For the most general case, a factor K_p might have been included in the term giving the attenuation due to the inner conductor to account, for instance, for tinned conductors. This has been omitted in the interest of clarity.

Form of Inner Conductor. The factor, k_1, has been determined by A. L. Meyers[5] in a solution obtained by an extension of the theoretical results of T. Levi-Civita.[6] He gives values of k_1 for different values of m the number of closely-adhering strands in the outer layer of the stranded conductor having a total number of strands, n. These values are recorded in Table I.

The factor K_s is not amenable to calculation since it depends, to some extent, on the contact resistance of the inner conductor, and therefore varies with the material used and its cleanliness, and probably varies somewhat with frequency. Based on practical observations, a value of 1.30 is suggested as appropriate for the case of a reasonably clean 7-strand conductor in a solid-dielectric cable at all frequencies.

A similar factor may be taken for well-formed conductors having a greater number of strands, but the practical observations to support this are not extensive. In exceptional cases, the inner conductor may take the form of indented or corrugated longitudinal tapes or of helically-lapped tapes. The treatment proposed in such cases is outlined in the following section.

Form of the Outer Conductor. The factor, K_b, is intended to take care of deviations in the form of the outer conductor from the ideal cylindrical form. These deviations usually take one or other of the following forms:

1. Indented or corrugated longitudinal tapes.
2. Helically-lapped wires or tapes.
3. Braided wires, tapes, or bunched strands.

The factor corresponding to the first case can be estimated with sufficient accuracy by increasing the resistance of the equivalent ideal cylinder in proportion to the increase in length of the return path and the reduction in its effective periphery. The second case now is used rarely at high frequencies owing to the high attenuation and instability induced by poor contact resistance between neighboring elements except where a binding tape can be used to short circuit the neighboring ropes. Another exception is the overlapped tape applied with short lay, which tends to be unstable at low frequencies, but approaches the characteristics of a cylindrical conductor when frequencies are higher than about 10 megacycles per second. The case of braided conductors is of most practical importance.

The conditions of current flow in braids are far too complicated to be solved theoretically, although an elementary treatment has confirmed the effect of most variables of designs. Practical tests have shown that the use of short lays for the wire-braiding increases the radio-frequency resistance of the outer conductor, and that there is an optimum value for the filling factor of the braid, although this is not very critical provided that the braid is neither overfilled nor seriously under-filled. It also has been shown experimentally that the resistance factor increases as the core diameter increases. The following values of resistance factor based on practical observations are suggested as applying to present-day production.

Core Sizes Inches Diameter	K_b
0.25	2.0
0.50	2.5
0.75	3.0
1.00	4.0
1.50	5.0

These factors may be applied at all frequencies up to 3,000 megacycles per second. At higher frequencies up to about 10,000 megacycles per second contact resistance between wires appears to be responsible for the instability and the higher values of resistance which have been observed, and it may be found necessary to use silver-coated wires to achieve the resistance factors quoted before.

Material of Outer Conductor. In equation 2, the resistance factor relating to the material of the outer conductor is referred to that of the inner. For the case

Table III

Material	Symbol	Thermal Resistivity (Degrees Centigrade Cm/Watt)
Ground	G_g	120
Polyethylene	G_d	450
Servings (bituminized hessians or cottons)	G_s	500
Polyvinyl resin sheathings	G_s	1,200
Still air	G_a	4,100

of the homogeneous conductor at very high frequencies it is obvious that $K\rho$ is equal to the square root of the ratio of the resistivities of the outer and inner conductors.

For the case of bimetallic conductors, the resistance varies with frequency in a manner different from that of homogeneous conductors because an increasing proportion of the current flows in the outer layer as the frequency is raised. A theoretical solution for the resistance at very high frequencies by H. R. F. Carsten has been used.[1]

An important case of bimetallic conductors is involved in the use of tinned copper. A tin thickness of 0.2 mil has been assumed and the calculated values of $K\rho$ for various frequencies are given in Table II.

The application of this factor to tinned copper wire, as used in braids, is admittedly questionable, but it has been found to give a reasonable approximation to measured values.

The following values apply to materials which are of interest in radio-frequency cable construction:

Material	Resistivity in Ohm-centimeter	K_ρ
Copper	1.724×10^{-6}	1
Aluminum	2.825×10^{-6}	1.28
Lead	21.1×10^{-6}	3.5
Lead-tin alloy used in tinning	13.5×10^{-6}	(See Table II)

Permittivity of Insulant. The material of primary interest in flexible cables is polyethylene and this has a permittivity of 2.30 at all useful frequencies. However, in view of the fact that minute air films at the inner conductor have a marked effect on the effective permittivity of the cable insulation, a figure of 2.25 has been assumed for the practical case.

For the case of air-spaced and semi-air-spaced cable, the effective permittivity will vary with the construction and the following values are average practical values:

Semirigid air-spaced cables—1.1
Expanded polyethylene cables—1.2–1.3
Semi-air-spaced flexible cables—1.4–1.75

Power Factor of Insulant. The power factor of polyethylene is usually very low and rises slowly with increasing frequency. The presence of minute quantities of oxidation products may superimpose an absorption band spreading over a wide frequency range and having its peak at about 100–200 megacycles per second. As a consequence the temperature coefficient may be negative at low frequencies and positive at high frequencies.

For theoretical studies, a figure of 4×10^{-4} has been assumed for all frequencies and temperatures. This value is not usually exceeded in present-day production, except perhaps for a combination of extremely high frequency and temperature.

Attenuation of Balanced Cables

At very high frequencies the attenuation is given approximately by the expression

$$\alpha=\frac{2.287\times10^{-7}\sqrt{\kappa\rho_1 f}}{\log_{10}\left(2\nu\,\dfrac{1-\sigma^2}{1+\sigma^2}\right)}\left\{\frac{K_sK_p}{d}+\frac{4\sigma^2K_\rho}{D}\right\}+1.047\times10^{-10}\sqrt{K}f\tan\delta \text{ nepers per centimeter} \quad (3)$$

where

$\nu=2h/k_1d$
$\sigma=2h/D$

In equation 3 the two components of the first term refer to the losses in the conductors and screen respectively while the second term represents the dielectric loss. The significance of the empirical constants remains as in the previous section except where noted in the following.

Unscreened Balanced Cables. In this case $\sigma = 0$ so that the attenuation becomes

$$\alpha=\frac{2.287\times10^{-7}\sqrt{\kappa\rho_1 f}}{\log_{10}2\xi}\left(\frac{K_sK_p}{d}\right)+1.047\times10^{-10}\sqrt{K}f\tan\delta \text{ nepers per centimeter} \quad (4)$$

A doubt will often exist as to the appropriate value to assume for the effective permittivity. In the case of flexible solid-dielectric cables provided with belt insulation a value very little below that of the dielectric material itself is appropriate.

Carson[7] has given a formula for the proximity factor at very high frequencies

$$K_p=\frac{\nu}{\sqrt{\nu^2{}_{-1}}} \quad (5)$$

Rigid Screened Balanced Cables. In most practical designs, the proximity factor may be assumed to be unity in view of the proximity of the screen to the conductors.

Braided Flexible Balanced Cables. Where the screen consists of wire braid, it has been found that the attenuation depends greatly upon the contact resistance between the wires, in marked contrast to the coaxial case. In such cases the total attenuation at ultra high frequencies will often increase tenfold in a matter of days if the cable is left undisturbed. A partial recovery occurs if the cable is flexed vigorously, but the improvement is not maintained.

Table IV. Assumed Values of Convection Constant, K_c

Ratio of Air-space, Diameters, D_1/D_2	$K_c\times10^4$
0	16.0
0.2	10.5
0.4	5.8
0.6	3.1
0.8	1.4
1.0	0

In England it is customary to provide a metallized paper underneath the wire braid. This reduces the instability very markedly, but the attenuation is still appreciably higher than that given by equation 3.

It is recommended that measured values of attenuation should be used to calculate the power ratings of flexible balanced cables. The increment of attenuation over the theoretical value may safely be attributed to imperfections in the screen.

ESTIMATION OF THERMAL DISSIPATION

In the dissipation of heat from source to sink, conduction, radiation, and convection play their part. Since the two latter processes are not linear with temperature it is necessary to summate the temperature drops over different parts of the cable system to obtain the relationship between the heat dissipated and the total temperature rise. The problem is further complicated by the fact that, in the present case, there are various heat sources located at different parts of the cable system.

Thermal Resistance of Cable Insulation

Solid-dielectric Coaxial Cable. The thermal resistance per unit length of a long straight cylinder of material corresponding to the insulation of the cable is given by

$$S_d=\frac{G_d}{2\pi}\log_e(D/k_1d) \text{ degrees centigrade, centimeters per watt} \quad (6)$$

The appropriate value of G_d is given in Table III, in which the value proposed is higher than that of polyethylene itself and is based on actual cable measurements. The enhanced value is attributed to poor, and variable, thermal contact between the insulation and the adjoining conductors. The same remarks apply to

Table V. Assumed Values of Heat Emission Constant, k

Surface Condition	Constants of Heat Emission, $k\times10^4$ for Various Cable Diameters (cm) 1	2	3	5	7	10
Polyvinyl chloride sheathed or served	7.0	6.0	5.3	4.7	4.6	4.5
Plain lead sheath	6.1	5.1	4.6	4.2	4.1	4.0
Bright wire finish	5.2	4.2	3.9	3.8	3.7	3.5

the figures given for the polyvinyl resins.

Air-spaced Coaxial Cable. In this case heat transfer occurs by conduction, radiation, and convection. It is necessary to summate the heat flows corresponding to each process due to a given temperature difference, in a manner similar to that used to calculate the heat transfer from cables in ducts (see reference 2, page 530). This is repeated for several temperature differences over the interesting range, to yield the effective thermal resistance of the insulation over the same range.

The following equations apply

Conduction Loss

$$H_d=\frac{2\pi(\theta_1-\theta_2)}{G_a\log_e(D_2/D_1)}\text{ watts per centimeter}\tag{7}$$

Radiation Loss

$$H_r=\frac{4\pi D_1.\sigma(273+\theta_2)^3E_1E_2(\theta_1-\theta_2)}{E_1+E_2-E_1E_2}\text{ watts per centimeter (approximate)}\tag{8}$$

Convection Loss

$$H_c=K_cD_1^{3/4}(\theta_1-\theta_2)^{5/4}\text{ watts per centimeter}\tag{9}$$

where

σ = Stefan's constant $=5.71\times10^{-12}$

E = emissivity of the surface which is boundary to the air space

D = diameter of the boundary surface, centimeters

θ = temperature of the boundary surface, degrees centigrade

and the suffixes 1 and 2 refer respectively to the inner and outer surfaces which enclose the air space.

Table VI. Rating Factors for Various Operating Conditions

Ambient Temperature	Maximum Permissible Temperature 85°C.	75°C.	65°C.
40	1.58	1.20	0.82
55	1	0.63	0.29
70	0.45	0.13	
85	0		

The relationship between the constant K_c and the ratio of the dimensions of the air-space is given in Table IV, the values being taken from the British Electrical and Allied Industries Research Association report already quoted.[2]

In the absence of experimental data, the following values for thermal emissivity have been assumed:

Copper	0.10
Aluminum	0.25
Lead	0.25
Polyethylene (white)	0.40
Polyethylene (black)	1.00

Balanced Cables. An approximate solution for the thermal resistance between the two conductors and the screen of a balanced cable is as follows

$$S_d=\frac{G_d}{2}\log_e\left(\frac{\nu}{2\sigma^2}(1-\sigma^4)\right)\text{ degrees centigrade, centimeters per watt}\tag{10}$$

where

$\nu=2h/k_1d$

or

$\sigma=2h/D.$

This assumes that the screen is an isothermal. The same equation could be applied to unscreened balanced cable, with little loss of accuracy. In this case D represents the diameter over the solid-dielectric belt.

Thermal Resistance of the Cable Coverings

The thermal resistance of unit length of the coverings is given by the equation

$$S_c=\frac{G_c}{2\pi}\log_e D_2/D_1\text{ degrees centigrade, centimeters per watt}\tag{11}$$

where D_1 and D_2 are respectively the inner and outer diameters of the covering. In the case of armored cable, the armor wires or tape may be considered to have negligible temperature drop and the total thermal resistance will be the sum of the two terms corresponding to the bedding and outer servings.

Thermal Resistance External to the Cable

Cables Installed in Air. Comprehensive tests by the National Physical Laboratory have shown that the thermal emission from the surface of cables in air can conveniently be expressed by the empirical relationship.

$$H_\theta=\frac{Ak}{l}\theta_s^n\text{ watts per centimeter}\tag{12}$$

where A is the surface area (squared centimeters) and l is the length (centimeter). It has been found that a value of 5/4 for the index n satisfies practical conditions best.

The effective thermal resistance external to unit length of the cable is therefore given by

$$S_a=\frac{1}{\pi D_s\theta_s^{1/4}k}\text{ degrees centigrade, centimeters per watt}\tag{13}$$

The values of k for various conditions of surface are used in the present calculation shown in Table V and are based on information given in the British Electrical and Allied Industries Research Association report.

It is difficult to deal with the case of grouped cables theoretically, because, in contradistinction to the power cable case, it will be rare that similar cables carrying the same load will be involved. To show the order of effect involved the following observations may be made. It has been found that for two cables touching one another the appropriate value of k is that corresponding to a single core, reduced by 30 per cent and for three cables touching, the value of k is reduced by about 40 per cent.

Cable Installed in Ground. The thermal resistance of the ground is given approximately by

$$S_g=\frac{G_g}{2\pi}\log_e\frac{4l}{D_s}\text{ degrees centigrade, centimeters per watt}\tag{14}$$

where l is the depth of burial.

Thermal Dissipation of Cable Systems

In a radio-frequency cable, the inner conductor, the insulation, and the outer conductor are all sources of heat loss. In the case of a coaxial cable with a homogeneous insulation, it may be shown that the distributed loss in the insulation is accurately replaced by two lumped losses, each equal to one half of the total dielectric loss, located at either boundary. In the case of balanced cable it would appear to be reasonable to consider the total dielectric loss to be lumped at the conductors, although this obviously gives a slight over-estimate of the temperature drop.

Then, putting $\alpha_{c1}=k_1\alpha$, and $\alpha_d=k_d\alpha$, we may write, using the principle of superposition.

$$\theta_c=H_\theta[S_d(k_1+k_d/2)+S_c+S_a]\tag{15}$$

for a coaxial cable, and

$$\theta_c=H_\theta[S_d(k_1+k_d)+S_c+S_a]\tag{16}$$

for a balanced cable.

Since S_a varies with θ_s and, in the case

Table VII. Principal Dimensions of Solid Dielectric Cables

Characteristic Impedances: 50 and 75 ohms

Core Diameter, Inches	Diameter Over Braid, Inches	Diameter Over Sheath, Inches

0.250	0.285	0.345
0.500	0.540	0.630
0.750	0.790	0.900
1.00	1.040	1.180
1.500	1.540	1.740

of air-spaced cable, S_d varies with $(\theta_c - \theta_r)$, these equations are best solved graphically by plotting $(\theta_c - \theta_r)$, $(\theta_r - \theta_s)$, and θ_s against H_θ.

In the case of solid-dielectric cables buried in the ground this problem does not arise and the temperature rise of the inner conductor may be calculated directly, thus, for a coaxial cable

$$H_c = \theta_\theta / [S_d(k_1 + k_d/2) + S_c + S_g] \qquad (17)$$

ESTIMATION OF THERMAL RATING

Fundamentally the heat sources in a cable carrying a current I at voltage E are

$$I^2R + E^2\omega C \tan \delta \text{ watts per centimeter}$$

and this total heat loss must be equated to the heat dissipation calculated in the manner developed in the previous section. This method can conveniently be applied directly in cases where the loss due either to voltage or to current predominates. This condition often applies, for instance, in induction heating at low frequencies. For the general case it seems preferable to base the thermal rating on the mean power which can be transmitted continuously through a matched system, to cause a given maximum conductor temperature in a given ambient in a cable free from any longitudinal alleviation of temperature. This standard rating is a particular form of the general case considered before in which the ratio of the voltage and current is fixed and made equal to the characteristic impedance of the cable. From this basic rating, new ratings can be developed, by the application of "rating factors" to take care of variations in the operating conditions, and these are discussed later.

Determination of Basic Rating

For a matched system the power P transmitted along the cable is given by the expression

$$P = P_0 \epsilon^{-2\alpha x}$$

where x is the distance from the input end. The heat dissipation H at any point along the line can therefore be expressed in terms of the power being transmitted by substitution in the relationship

$$H = -\frac{d_P}{dx} = \frac{-d(P_0\epsilon^{-2\alpha x})}{dx} = 2\alpha P_0 \epsilon^{-2\alpha x} \qquad (18)$$

The dissipation H_θ corresponding to a specified maximum temperature rise θ is therefore given by the maximum value of the foregoing expression, or

$$P_\theta = \frac{H_\theta}{2\alpha} \qquad (19)$$

Maximum Temperature of Operation

In fixing the maximum permissible temperature of operation, several factors must be considered.

1. The temperature of the insulation must not approach the point at which softening occurs, so permitting displacement of the inner conductor or distortion of the cable.
2. Any chemical or physical action, which might deteriorate the insulation or impair the effectiveness of the waterproof coverings, must not be excessive.
3. Temperatures must be limited to avoid trouble due to differential expansion of the component materials used in the construction of the cable.

In the case of polyethylene-insulated cables, a maximum temperature of 85 degrees centigrade has been adopted in England for general use in the armed services. At this temperature the thermoplastic insulant is softened to the extent that it will not withstand severe mechanical stresses, but is satisfactory for normal usage. Some deterioration also will be experienced at these temperatures due to migration of the plasticizer in normal types of polyvinyl-resin sheathings. This causes a hardening of the sheathing material and an increase in the power factor of the insulant to an extent which may be serious at the higher frequencies. Sheathing materials with nonmigratory plasticizer should be used in such cases.

For commercial operation, a somewhat lower temperature of operation is desirable.

In air-spaced cables, the mechanical stresses on the insulant due to the inner conductor are inevitably higher than in solid-dielectric cables, and it is desirable that such cables should be rated still more conservatively.

In the present paper, basic ratings have been drawn up for three interesting ranges of cable and these have all been based for ease of comparison, on the same maximum temperature rise of 30 degrees centigrade. Other conditions of operation may, with little loss of accuracy, be met by multiplying the standard ratings by the rating factors, as will be indicated.

Ambient Temperature

The ambient temperature has a marked effect on the rating in view of the fact that the maximum permissible temperature may not be very much higher. The standard ratings for solid-dielectric cable have been based in the present instance on tropical use for which an ambient of 55 degrees centigrade has been assumed. Rating factors corresponding to use in temperate climates or in equipment are given in Table VI. The schedule proposed is based on the average of a wide range of cables. It should be noted that for use in equipment the ratings correspond to natural ventilation and if forced circulation is adopted some increase in rating might be permitted.

Effect of Modulation and Load Factor

It may be shown that for a system which is amplitude modulated by a factor, m, that the power transmitted and the heat lost in the cable is increased by a factor $1 + m^2/2$.

In practice the modulation varies usually between wide limits, but if the variation is reasonably rapid compared with the time-constant of the cable, the average value may be used. However, in general, equipment will be required to satisfy some arbitrary test involving operation for a given time at a given modulation and these conditions should set the requirements for the cable rating.

For pulse-modulated radio frequency, the mean power determines the rating and this may be taken as equal to peak power × pulse length × repetition frequency.

Calculations show that the thermal time-constant of solid-dielectric radio frequency cables in air varies between three minutes for a cable of 1/8 inch diameter over the insulation to about 90 minutes for a $1^1/_2$ inch cable. The time constant might be expected to vary at a rate proportional to the diameter raised to a power between 1.75 and 2. The time constant of buried cables is considerably higher, but since the cable ends will generally be above ground, advantage can rarely be taken of this condition. The figures just quoted show that the opportunities to increase the short-time rating of cables to take care of low load factors are extremely limited.

Effect of Standing Waves

The effect of standing waves on the temperature rise is very complex, and it is

Table VIII. Assumed Values of Attenuation for Solid Dielectric Cables, in Decibels per 100 Feet at 100 Megacycles per Second

Core Size, Inches	50-ohm Cables				75-ohm Cables			
	α_{c1}	α_d	α_{c3}	(Total) α	α_{c1}	α_d	α_c	(Total) α
0.125	2.95	0.166	1.38	4.45	3.01	0.166	0.922	4.10
0.250	1.47	0.166	0.692	2.33	1.51	0.166	0.461	2.14
0.500	0.737	0.166	0.461	1.36	0.752	0.166	0.288	1.21
0.750	0.491	0.166	0.346	1.00	0.502	0.166	0.231	0.90
1.000	0.368	0.166	0.346	0.88	0.376	0.166	0.231	0.77
1.500	0.245	0.166	0.307	0.72	0.251	0.166	0.192	0.61

difficult to express it in a concise form. The components of conductor and dielectric loss will vary along the line according to similar periodic functions which are 180 degrees out of phase and their combined effect will vary with the impressed frequency and the cable design. Two limiting cases will be recognized:

1. When the frequency is so high and the longitudinal transfer of heat is so effective that periodic maxima and minima of temperature tend to disappear. In this case it can be shown that the power transmitted along a cable of attenuation constant α, with a standing-wave ratio $s = E_{max}/E_{min}$ on the line, is given by

$$P=P_0 / \left[\epsilon^{2\alpha x}+\frac{(s-1)^2}{2s}\sinh 2\alpha x\right] \tag{20}$$

The maximum heat dissipation is therefore given by

$$H_\theta=\left(-\frac{dP}{dx}\right)_{x=0}=2\alpha P_0 \frac{s^2+1}{2s}\Bigg] \tag{21}$$

2. When the longitudinal transfer of heat along the cable can be neglected. Then remembering that the dielectric loss is proportional to the square of the voltage and the conductor loss is proportional to the square of the current, and putting $\alpha_d=k_d\alpha$, we may write for the maximum heat dissipation

$$H_\theta=2\alpha P_0\left[\frac{k}{s}+(1-k_d)s\right]$$

or

$$H_\theta=2\alpha P_0[ks+(1-k_d)/s]$$

whichever is the greater.

The most severe case occurs when either the conductor loss or the dielectric loss predominates. In this case, the dissipation will be increased, relative to a matched system, by a factor equal to the standing-wave ratio. The safe rating will be reduced correspondingly, or

$$P_0=\frac{H_\theta}{2\alpha s} \tag{22}$$

It is recommended that this criterion be used unless a more rigorous study can be made.

Voltage Ratings

The type of insulant used in radio-frequency cables usually precludes the appearance of any technical thermal instability process. The normal case of dielectric heating due to the applied voltage has been considered in the previous section, and it only remains to consider the effect of any nonlinear mechanism which may arise. Such limitations are most likely to arise for low-frequency applications or for the case of pulse-modulated systems.

Since the performance under transient voltage of solid-dielectric cables is quite different from that of air-spaced cable, the two cases are considered separately. It is useful however to make a preliminary survey of the nature of the voltage stresses which may be imposed on a transmission feeder.

The peak voltage due to a mean unmodulated power P_0 transmitted along a cable into a matched load, is given by the expression

$$E_p=\sqrt{2Z_0P_0} \text{ volts (peak)} \tag{23}$$

The ratio of the maximum voltage on the cable to the input voltage when the line is not correctly terminated at the load end depends upon the electrical length and attenuation of the line, and the nature of the mismatch. However this ratio cannot exceed the value of s, the standing wave ratio, and it is desirable to use this value for the general case, unless the special circumstances of an application justify a closer study.

If the input power is modulated by a factor m, the peak voltage will be increased by a factor $(1+m)$. For a pulse-modulated power application, the requirement for the cable usually will be expressed in terms of the peak power to be transmitted, and the peak voltage may be calculated directly.

Overvoltages, beyond the value calculated for the steady-state condition, as calculated before, will appear on the cable when the transmitter is switched, or when the constants of the terminating circuits are altered, whether by design or by accident. In certain cases, the antenna will be exposed to the possibility of a lightning stroke and although in such cases lightning protection would be provided, the voltages on the cable due to the resultant mismatch will be liable to exceed the maximum voltage which is normally present on the cable.

The maximum stress, g, in a coaxial cable with perfect cylindrical electrodes is given by

$$g=\frac{2E}{d\log_e D/d} \text{ volts per centimeter} \tag{24}$$

A. L. Meyers[8] gives a convenient expression for the effect of stranding, namely

$$g=\frac{2k_2E}{d\log_e D/k_1d} \text{ volts per centimeter} \tag{25}$$

where k_1 and k_2 are constants for any given strand formation. Some calculated values of these constants are given in Table I.

For a given voltage, the minimum value of g, with perfect cylindrical conductors, is attained when D/d has the value ϵ or 2.72. A somewhat lower value applies in the case of stranded conductors. The stress, g, may be converted readily in terms of the mean power by combining equations 23 and 24.

$$g=\frac{\sqrt{(120P_0\log_e D/d)}}{k^{1/4}}\times\frac{2}{d\log_e D/d}$$

$$=\frac{\sqrt{(480P_0)}}{k^{1/4}}\times\frac{1}{d\sqrt{(\log_e D/d)}} \text{ peak volts per centimeter} \tag{26}$$

This has a minimum value when $D/d=\sqrt{\epsilon}=1.65$, which corresponds to a characteristic impedance of 30 ohms for an air-spaced cable or 20 ohms for a polyethylene-insulated cable. This condition is rarely attained in practice because it is rather far removed from the condition for minimum attenuation.

Solid-dielectric Cables

For solid dielectric cables, we may usually dismiss the problem of transient voltages because the intrinsic surge strength of solid materials is usually extremely high compared with that of gases. Davis, Austen and Willis Jackson[9] have reported strengths for polythene of 1,650–2,000 kv per centimeter for single impulses and values of 1,000 kv per centimeter for more than 400 repeated pulses.

It has been established that minute

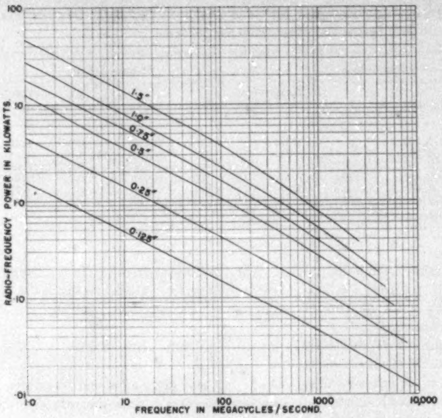

Figure 1. Power rating of some solid-dielectric flexible cables

Characteristic impedance, 50 ohms

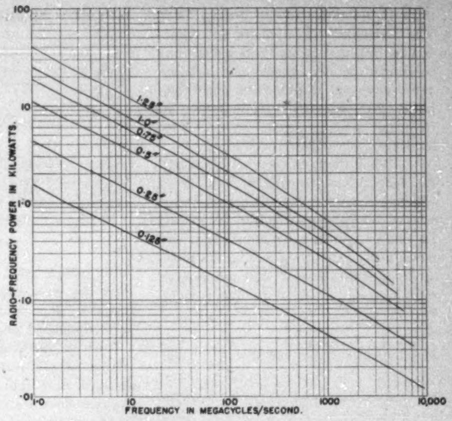

Figure 2. Power rating of some solid-dielectric flexible cables

Characteristic impedance, 75 ohms

cavities, in the form either of discrete bubbles or films in the neighborhood of the conductor, are often present in this type of cable. It has further been shown, by electrical tests at power frequencies and by visual tests at radio frequencies up to 2 megacycles per second that these cavities are the seat of electrical discharges when a certain critical voltage swing is exceeded. It is probable that this critical voltage does not greatly vary with frequency, certainly up to a few hundred megacycles per second. There is further limited evidence that the energy loss per cycle due to such discharges is of the same order, for a given impressed voltage, at power and radio frequencies. These discharges may cause direct electrical breakdown by disintegration of the molecules of the insulating material, or may cause overheating of the insulation by the superposition of the local energy loss on the general loss due to the cable attenuation. It has been proposed[3] that the radio frequency voltage rating should be equal to the power-frequency test voltage corresponding to a discharge of 2×10^{-12} coulombs for a 70-centimeter cable test piece.

It is inevitable, from the nature of the imperfections referred to, that the quality of cable judged in this way should vary within relatively wide limits. It has been found in England that the bulk of production of polyethylene radio-frequency cable is free from discharge at test voltages corresponding to 50 kv peak per centimeter, and that this discharge level is maintained during life when subjected to heating cycles. It is therefore proposed that the voltage rating of solid-dielectric cables should be based on a peak stress of 50 kv peak per centimeter, in the absence of specifications calling for a discharge initiation level which is appreciably higher than this value.

Since the criterion for the appearance of recurrent discharges is the total swing of voltage applied to the cable, the corresponding stress for cables subjected to unidirectional pulses is 100 kv per centimeter calculated from the total voltage swing of the pulse.

Air-spaced Cables

Considerable literature exists on the breakdown of air at high frequencies, although the consistency between the results obtained by different authorities is, at first sight, only fair. The probable reason for this will be revealed in the succeeding paragraphs.

Tested between sphere gaps in the region from 100 kc per second to 10 megacycles per second there is a drop in the breakdown strength of air, as compared with the 50 cycles-per-second value, of an amount not exceeding 20 per cent. Alford and Pickles[8] found no difference between breakdown values at 60 cycles-per-second and 13 megacycles per second whereas Cooper[9] has recently reported a reduction of 30 per cent, as compared with the direct voltage strength, at frequencies of 2,800 and 9,800 megacycles per second. The earlier results in the neighborhood of 1 megacycle per second have been attributed to the formation of a space charge due to the limited mobility of the positive ions. The precise band over which the process operates would appear to vary with the electrode configuration.

For needle gaps and for electrodes comprising point and plane, the reductions in strength, as compared with power-frequency values, are even more marked. Values of breakdown strength as low as 30 per cent of the 50-cycles per second value have been reported. This reduction of strength would again appear to be limited to the frequency band from 100 kc to 10 megacycles per second.

The effect of increased gas pressure has not been investigated widely, but tests in the neighborhood of atmospheric pressure have indicated that the normal air-density correction holds for radio frequencies of the order of a megacycle per second.

In dealing with the question of the electrical strength of air-spaced cables, it would appear that no form of electrical discharge can be tolerated. Two distinct conditions may be recognized.

In the first, the conductor surfaces are free from local irregularities and the variation of stress is restrained. The stresses in such cases are usually amenable to exact calculations. In the absence of comprehensive tests on air-spaced coaxial cables at radio frequencies, it seems safer to assume that the electrical strength at all radio frequencies of a cable satisfying these conditions may be about 20 per cent lower than the power-frequency strength.

In the second case there may be present

local stress concentrations, such as might be caused by burrs on the conductor, by small metallic slivers or by the presence of high-permittivity materials in the air space. It is, of course, quite impractical to attempt to calculate the maximum stress in these circumstances. It is therefore recommended that a further criterion be applied to determine the safe operating level of voltage. The critical power-frequency voltage, corresponding to the appearance of discharges, should be determined by one of the several methods which have been developed. The discharge detector used must be highly sensitive and the testing equipment itself should be free from discharge. This discharge initiation voltage should be taken as the ultimate strength of the cable at all radio frequencies. The same principles should be applied to the consideration of cables in which elevated gas pressures are used.

It is recommended that the electrical strength of the cable, calculated as before, should allow a factor of safety of not less than four on the maximum voltage normally arising on the cable, due allowance being made for the maximum permissible modulation coefficient and standing wave ratio. This factor of safety is intended to take care of switching transients.

Practical Application of Proposed Methods

The methods proposed in the preceding sections have been applied to establish the rating of three interesting classes of cable, namely:

1. 50-ohm flexible polyethylene-insulated cables.
2. 75-ohm flexible polyethylene-insulated cables.
3. 75-ohm air-spaced semirigid cables.

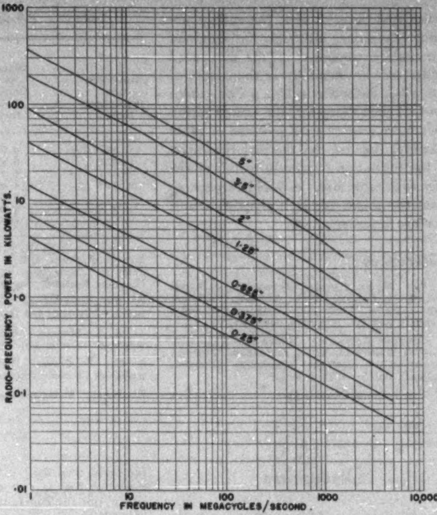
The individual cables in these classes are designated by their diameter over the insulation. The construction of the cables of the first two classes are in general accord with the United States Army-Navy specification for radio-frequency cables *JAN-C-17*. As proposed in the section The Attenuation Coefficient of Cables, an allowance of 10 per cent has been added to the attenuation coefficients quoted to allow for variations in materials and construction.

SOLID-DIELECTRIC FLEXIBLE CABLES

The 75-ohm cables are assumed to have a solid inner conductor while the 50-ohm cables have a 7-strand conductor. Both ranges have plain copper wire braids. The principal dimensions are given in Table VII.

Figure 3. Power rating of some air-spaced cables

Characteristic impedance, 75 ohms



The components of attenuation assumed for these cables are given in Table VIII for a frequency of 100 megacycles per second. Corresponding values at other frequencies may be estimated readily on the assumption that the conductor losses vary as the square root of frequency, and that the dielectric losses are directly proportional to the frequency. The attenuation coefficients of the 75-ohm cables are about 10 to 15 per cent lower than those of the corresponding 50-ohm cable because the latter design assumes the use of a stranded conductor.

The power ratings for a matched load are plotted against frequency in Figures 1 and 2 for the 50- and 75-ohm cables respectively, for a maximum conductor temperature of 85 degrees centigrade, in an ambient of 55 degrees centigrade. A comparison of these figures shows that although the attenuation of the 50-ohm cables is higher, their power ratings are not less than those of the corresponding 75-ohm cables and are even 10 to 15 per cent higher for the larger cables. The difference is more marked at the higher frequencies where the dielectric loss is important. This result derives from the lower thermal resistance of the insulation of the 50-ohm cables, due to their lower diametral ratio, and from the fact that the thermal resistance external to the cable falls with increase in cable size whereas that of the insulation is of course unchanged.

75-OHM AIR-SPACED SEMI-RIGID CABLES

The cable type selected for the present theoretical study has a solid copper inner conductor and an extruded tubular return conductor of aluminum. This design lends itself to cable construction, is sufficiently flexible and robust for installation and has a transmission efficiency very close to the optimum obtainable. An effective permittivity of 1.10 and a power factor of 1×10^{-4} has been assumed. The principal dimensions and assumed attenuations of the range of cables studied are given in Table IX.

Figure 3 shows the mean power rating of these cables for a matched load over a range of frequencies. The assumed conditions were a maximum conductor temperature of 70 degrees centigrade, and an ambient of 40 degrees centigrade.

The calculations showed that the thermal resistance of the insulation was always many times that external to the cable, even with the larger cables where an enhanced degree of cooling of the inner conductor occurs due to convection. Consequently the outer conductor may be quite cool even when the inner conductor is very hot.

A rough comparison with the solid dielectric cables is possible because the maximum temperature rise above ambient is the same in each case. It will be noted that, size for size, the ratings are much the same, although the assumed attenuation constants of the air-spaced cables are very much lower than those of the solid dielectric cables. For cables above 1-inch diameter, the power rating rises more steeply with increase of cable diameter because the thermal resistance of the insulation continues to fall markedly with cable size. A 5-fold increase in diameter above one inch gives a 10-fold increase in power rating.

Table IX. Principal Dimensions and Assumed Attenuations of Air-Spaced Cable

Diameter over Insulation, Inches	Diameter over Aluminum Sheath, Inches	Diameter over Servings, Inches	Assumed Attenuation Decibels per 100 Feet at 100 Megacycles per Second

Discussion

L. F. Roehmann (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.): Mildner's paper is excellent, and I say that not as a compliment but as a statement of fact. Particularly, his relation (18) between imput power and heat dissipated is lucid and revealing. True, he had it published previously in the Journal of the Institution of Electrical Engineers but it is now sandwiched between a host of less relevant equations, and its fundamental importance is thus played down.

There are a few comments from a power cable engineer's point of view, as follows:

1. While the discussor, and very probably his colleagues in the power field, have no difficulty in understanding the theory, problems arise when specific constructions are discussed which are familiar to the "coaxial boys" but not to them. How are balanced cables made up? And particularly, what is a "rigid screen" in a flexible cable? One sentence, or two, would put the reader at ease.

2. In speaking of the thermal resistance from the source to the "sink," power cable engineers distinguish basically between two thermal resistances; the (volume) thermal resistance of insulation, covering, and so forth, and the surface thermal resistance. The first is characterized by volume thermal resistivity and geometry, the second by surface thermal resistivity and geometry. For some unaccountable psychological reason there is a tendency to misname the second term "surface emissivity" though the word emissivity should be restricted to its distinct meaning in connection with radiation. Curiously enough, Mildner succumbed to the same mistake. E in equation 8 for the radiation loss is correctly defined as emissivity, but the constant k in Table V is misnamed emission constant though it is, dimensionally, a surface thermal conductivity.

3. Power rating, as the outcome of the investigation, is given in kilowatt as a function of frequency. Does that mean that a cable, rated 1 kw, may carry 1 ampere at 1 kv and equally well 1,000 amperes at 1 volt? Assuredly not! But who bridges the gap to the power engineer's concept who talks of rating only in terms of amperes, for a given voltage class? Or is it tacitly understood, amongst the coaxial boys, that the cables mentioned may not be operated at voltages in excess of certain unspecified limits? After all, at the frequencies under consideration, the current concept still holds true though standing waves introduce a complication which does not exist at power frequencies. This complication, however, is taken care of by the author, somewhat summarily, in such a way that the ratings will be conservative.

R. C. Mildner: The following brief description of balanced cables may serve to clear the difficulties to which Roehmann has drawn attention.

In a balanced cable, the two conductors comprising the transmission line are disposed symmetrically relative to earth or to a surrounding screen. In England it is usual to insulate each conductor separately, to cable the two conductors together with a length of lay from 2 to 5 inches, and to fill with insulating material to circular cross section. A belt of insulating material is sometimes applied additionally. I believe that it is more usual in the United States to arrange that the two conductors lie parallel without lay in a single extrusion of insulating material. Such cables may be left unscreened, or, in the case of flexible cables, provided with a wire braid (in England usually with a metalized paper as well). In the case of semirigid cables a lead sheath may be used as a screen.

I regret that, in dealing with the thermal resistance external to the cable, I have used a nomenclature which may be considered unorthodox in the United States. But I cannot accept that the terms which I have used and which are accepted in England are less logical than those quoted above. I feel that Roehmann attaches too narrow a meaning to the word "emission". Furthermore he overstates his case in claiming that the constant k in Table V has the dimensions of a surface thermal conductivity. This is clearly incorrect because k must be multiplied by a nonintegral power of temperature and by a distance to give the heat dissipation.

I know that the concept of power as opposed to current rating often creates difficulties for a power engineer. The section paper entitled Estimation of Thermal Rating attempted to make the position clear. For a cable having a characteristic impedance of 100 ohms, a power rating of 10 kw implies that the cable may carry 10 amperes at 1,000 volts. If, as is usual at low and medium frequencies, the conductor loss predominates, then the value of 10 amperes may be considered as the current rating of the cable. If the dielectric loss is appreciable, the current rating will be increased above the value of 10 amperes in proportion as the dielectric loss due to the applied voltage is reduced. I do not think it is practicable to give the general case with greater precision. The principles quoted in the paper will permit particular cases to be studied with sufficient accuracy.

Damper Stabilized Instrument Servomechanisms

ALBERT C. HALL
MEMBER AIEE

SERVOMECHANISMS are increasing in importance in this period of military and industrial mechanization, and are found performing tasks of variety limited only by the imagination of the engineer. A type of servomechanism that is very useful in both the military and industrial fields is termed the "instrument servomechanism." This term was employed originally to denote a servomechanism in which the output power required was primarily that necessary to operate itself. For example, a servomechanism operating a position indicator is called an instrument servomechansim because with reasonable design, the power required by the indicator is only a fraction of the power required by the servomotor. However, in more and more applications good reasons were found for coupling additional equipment to instrument servomotors, until in many cases the load power requirements became substantial. Consequently, today the term "instrument servomechanism" is used broadly to denote servomechanisms of any kind that develop an output power not more than about one-tenth horsepower.

Since a servomechanism is a closed-cycle system and contains power amplifying elements, the possibility always exists that the servo will be unstable if designed improperly. The servo engineer must concern himself with this possibility and design the system to avoid instability. Today, moreover, the science of designing closed-cycle systems has developed to the point where a "yes" or "no" answer to the stability question no longer is sufficient. In addition to being stable, the servomechanism must possess such a margin of stability that transients will be well damped and that the values of system parameters can have a reasonable tolerance. Today, therefore, the statement that a servomechanism is stabilized signifies that a satisfactory margin of stability exists in the system.

The technique chosen to stabilize a servomechanism is determined largely by the choice of servomotor, which, in turn, is likely to be specified by the application requirements. In many cases the servomotor is chosen with little regard for its dynamic properties but from considerations of efficiency, size, adaptability, type of power available and serviceability. Occasionally it is possible to employ in the application a servomotor and controller elements with such dynamic properties that the servomechanism will be stable without the use of compensating elements. More often the characteristics of the servomotor and other components of the servomechanism are such that it is necessary to provide compensating elements in the system to enable it to meet its dynamic requirements.

The stabilizing methods in common use are the following:

1. Cascade compensation.
2. Feed-back compensation.
3. Load compensation.

Figure 1 illustrates, in block diagram form, these three stabilizing methods. In cascade compensation a portion of the controller in cascade with the other system components, is designed to correct the characteristics of the servomotor and the remainder of the controller. Feedback compensation signifies that an appropriate signal from some point of the system is fed back around those system components, the dynamic characteristics of which require modification. In the third method of compensation, termed "load compensation," the characteristics of the system are corrected by altering the dynamics of the servo load. While cascade and feed-back compensation have been treated thoroughly in other literature[1,3,4] little has been written on the subject of load compensation. The subject of this paper, damper stabilization of servomechanisms, is an example of load compensation.

The simplest method of load compensation is that of applying to the servomotor output shaft a torque (viscous friction) proportional to the angular rate of rotation of the servomotor. This method of compensation is inefficient since it requires a power loss proportional to the rate of rotation of the servomotor. A more efficient type of load compensation element that has been employed with considerable success with instrument servomechanisms is the damper. One type of damper called the "viscous damper" in this paper, comprises a mass coupled to the servomotor shaft by means of viscous friction, as illustrated diagrammatically by Figure 2. The power loss in this unit is negligible since at constant servomotor velocity the external mass turns at the same velocity as the servomotor, and no power is absorbed by the viscous friction. A second type of damper, called the spring-coupled damper, also is illustrated by Figure 2. Here the rotating mass is coupled to the servomotor by means of a spring as well as by viscous friction. The advantages that result from the addition of the spring are made clear in later sections of the paper.

An instrument servomechanism with either type of damper can be designed

---

Paper 49-79, recommended by the AIEE servomechanisms committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted November 8, 1948; made available for printing December 22, 1948.

ALBERT C. HALL is associate professor at the Massachusetts Institute of Technology, Cambridge, Mass.

The author is indebted to Miss Constance Boyd for computation studies on the viscous-damper servomechanism, to Mrs. Elizabeth Kimball who made most of the computation studies on the spring-coupled damper, and to Donald McDonald who contributed greatly to the development of these servomechanisms, particularly to the design of the controller amplifier.

to have a well-damped natural frequency of 15 cycles per second or higher, and a correspondingly high ratio of torque output to error (sensitivity factor). While the configurations of both the viscous and spring-coupled dampers have been used as vibration absorbers in open-cycle systems, their design is entirely different if optimum operation in a closed-cycle system is to be secured. It is the purpose of this paper to develop the design criteria of these damper mechanisms and to discuss and compare their performance.

Method of Analysis

The steady-state sinusoidal analysis is employed to determine the optimum design parameters of instrument servomechanisms that employ damper stabilization. This method of analysis, in common use today among servomechanism engineers, considers the response of the system to a sinusoidal input whose frequency is varied from zero to a value well above the system natural frequency. The object of servo synthesis is to so adjust the system parameters that over as large a frequency band as possible the ratio of the amplitude of the output to the amplitude of the input is constant and the phase angle between the output and input is small. The ratio of amplitudes generally has a maximum at some frequency, and it is necessary to limit the ratio of this maximum to the zero-frequency-amplitude ratio to about four-thirds if the system is to have a satisfactory margin of stability.

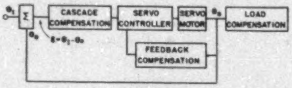

Figure 1. Servomechanism compensation methods

If the servo input and servo output are denoted θ_I and θ_o respectively it is common to express the sinusoidal characteristic of a servomechanism as $(\Theta_o/\Theta_I)(j\omega)$, written thus to emphasize the fact that the ratio is a function of the frequency ω. The ratio has vector properties and its amplitude may be written $|(\Theta_o/\Theta_I)(j\omega)|$.

A simplification of the analysis results if advantage is taken of the fact that the response of many servomechanisms is completely determined, except for a constant ratio, by the vector ratio of the servo output to the servo error. This vector ratio is called the transfer function and is written

$$\frac{\Theta_o}{E}(j\omega)=KG(j\omega) \tag{1}$$

in which K, the sensitivity factor, is invariant with frequency, while both the phase and magnitude of $G\,(j\omega)$ are functions of frequency. Since the error is given by

$$E(j\omega)=\Theta_I(j\omega)-\Theta_o(j\omega) \tag{2}$$

the system function $\Theta_o/\Theta_I(j\omega)$, is simply related to the transfer function by

$$\frac{\Theta_o}{\Theta_I}(j\omega)=\frac{KG(j\omega)}{1+KG(j\omega)} \tag{3}$$

The system response is thus completely determined by the transfer function, $KG\ (j\omega)$. Servomechanism synthesis, therefore, can be directed toward so prescribing the transfer function $KG\ (j\omega)$ that the system response has the proper characteristics.

The principles of servomechanism synthesis on the sinusoidal basis have been treated in other literature [1,3,4] and the analysis employed in this paper is no more than an application of these principles.

The method employed here is to plot the locus of the frequency dependent portion $G(j\omega)$ of the transfer function, and to determine from this plot the largest value of the sensitivity factor K, consistent with the maximum value of $|(\Theta_o/\Theta_I)(j\omega)|$, permitted by good servomechanism practice. With this restriction the system design is carried out to secure the desired system band width or the necessary system sensitivity.

The servomechanism design criteria may be summarized briefly as follows:

1. The amplitude response should be essentially flat to a frequency prescribed by the application requirements.
2. The maximum amplitude response should be not greater than about four-thirds its zero-frequency value.
3. The ratio of torque to error should be high with the actual value set by the system requirements.

The determination of the optimum system parameters for the damper-stabilized servomechanism is carried out with the foregoing criteria in view.

Design of Viscous-Damper-Stabilized Servomechanism

The synthesis of an instrument servomechanism stabilized by a viscous damper is considered first. Figure 3 represents the system diagrammatically. The torque developed by the servomotor is assumed to be proportional to the error except for the effects of a simple time lag and no viscous damping torques are considered to act upon the motor other than the one produced by the damper. While the latter assumption leads to slightly pessimistic results, the effect of viscous damping is a sufficiently small factor in the response of most high performance instrument servomechanisms to justify this simplification.

The differential equations of the system follow:

$$m=J_m\frac{d^2\theta_o}{dt^2}+f_A\frac{d\theta_o}{dt}-f_A\frac{d\theta_A}{dt} \tag{4}$$

$$f_A\frac{d\theta_o}{dt}-f_A\frac{d\theta_A}{dt}=J_A\frac{d^2\theta_A}{dt^2} \tag{5}$$

$$m+\tau_e\frac{dm}{dt}=k_e(N_I\theta_I-N_o\theta_o) \tag{6}$$

in which

θ_I, θ_o, and θ_A are the angular positions (as functions of time) measured with respect to a fixed reference of the servo input, the servo output, and the damper mass, J_A, respectively.

N_I and N_o are conversion constants relating the input and output of the servomechanism to voltages V_I and V_o, respectively, compared at the input to the servo controller.

f_A = torque acting upon the servomotor per unit relative velocity of the motor and the damper mass, J_A.

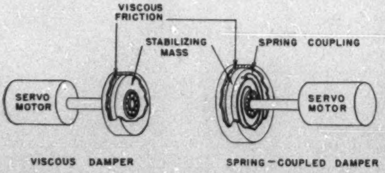

Figure 2 (left). Viscous and spring - coupled dampers

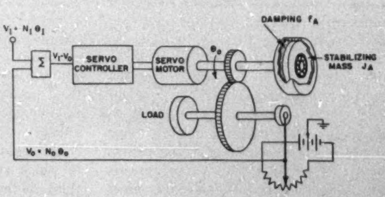
Figure 3. (right) Servomechanism stabilized by a viscous damper



J_A = moment of inertia of the stabilizing mass of the damper.

J_m = moment of inertia referred to the servomotor of those moving parts of the system coupled rigidly to the servomotor shaft.

m = torque of the servomotor as a function of time.

k_c = proportionality constant between the torque m, and the system error.

τ_c = time lag between the generation of the servo error and the development of a torque by the servomotor.

The differential equations of a linear system have equivalent relations in terms of sinusoidal functions. The sinusoidal equations are found by replacing each variable by its vector counterpart and replacing dt by $j\omega$. Thus equations 4, 5, and 6 can be rewritten

$$M = J_m\Theta_o(j\omega)^2 + f_A(\Theta_o - \Theta_A)j\omega \tag{4a}$$

$$f_A(\Theta_o - \Theta_A)j\omega = J_A\Theta_A(j\omega)^2 \tag{5a}$$

$$M(1+j\omega\tau_c) = k_c(N_I\Theta_I - N_o\Theta_o) \tag{6a}$$

in which Θ_I, Θ_o, Θ_A, and M are vectors expressing the amplitude and phase of the sinusoidal functions corresponding to the time function θ_I, θ_o, θ_A and m.

The preceding equations may be solved algebraically to determine the system transfer function.

$$KG(j\omega) = \frac{N_o\Theta_o}{N_I\Theta_I - N_o\Theta_o} = \frac{k_cN_o}{J_m(1+r)(j\omega)^2} \times \frac{1+\dfrac{J_A}{f_A}j\omega}{1+\dfrac{1}{1+r}\dfrac{J_A}{f_A}j\omega}\,\frac{1}{1+j\omega\tau_c} \tag{7}$$

in which

$$r = \frac{J_A}{J_m} \tag{8}$$

The system function is related to the transfer function by

$$\frac{\Theta_o}{\Theta_I}(j\omega) = \frac{N_I}{N_o}\,\frac{KG(j\omega)}{1+KG(j\omega)} \tag{9}$$

The ratio N_I/N_o is a constant, independent of frequency.

It is convenient to transform equation 7 by changing the frequency variable. If a new frequency variable u is defined as

$$u = \tau_d\omega \tag{10}$$

where

$$\tau_d = \frac{1}{1+r}\,\frac{J_A}{f_A} \tag{11}$$

Equation 6 can be rewritten

$$KG(ju) = \frac{k_cN_o\tau_d^2}{J_m}\,\frac{1}{ju(1+ju)} \times \left[1+\frac{1}{j(1+r)u}\right]\frac{1}{1+j\dfrac{\tau_c}{\tau_d}u} \tag{12}$$

The form of equation 12 emphasizes the fact that the sensitivity factor is

$$K = \frac{k_cN_o\tau_d^2}{J_m} \tag{13}$$

and the frequency dependent portion of the transfer function $G(ju)$ is given by

$$G(ju) = \frac{1}{ju(1+ju)} \times \left[1+\frac{1}{j(1+r)u}\right]\frac{1}{1+j\dfrac{\tau_c}{\tau_d}u} \tag{14}$$

The usual method of studying such a function is to plot the locus of the frequency dependent function $G(ju)$ in the complex plane for each interesting combination of system parameters, and to so determine the sensitivity factor K, that the maximum value of $KG/1+KG$ does not exceed about four-thirds. In this particular case the number of loci can be substantially reduced if it is assumed that the time lag τ_c, can be made sufficiently small to be neglected. In most practical applications it is possible to so design the controller that the time lag τ_c is negligible. However, the possibility that the time lag may be appreciable should not be disregarded, and a permissible limit on its magnitude is determined in the latter part of this section of the paper.

When $\tau_c = 0$, Figure 4 is a plot of the loci of equation 14 for four values of r, the ratio of the moments of inertia J_A/J_m. The margin of stability of the system for a particular value of r is indicated by the proximity of the corresponding locus and the negative real axis. The sensitivity factor K should be adjusted so that the margin of stability is adequate as indicated by the maximum value of the amplitude response. The proper value of K can be determined by a simple graphical construction (reference 1, page 47) based upon the fact that if the amplitude response of the system is a constant, the locus of the transfer function is a circle. By this means it is easily shown that if r is two or four, respectively, it is not possible to so choose the sensitivity K, that the maximum value of $|(\Theta_o/\Theta_I)(j\omega)|$ is less than two or one and one-half, respectively.

On the other hand, if r is equal to or greater than six the sensitivity can be adjusted to limit the maximum amplitude ratio to four-thirds. The curves of Figure 5 were determined from the loci of Figure 4 and summarize the effect of sensitivity and ratio of moments of inertia upon the maximum amplitude ratio. Conservative servomechanism design in most cases would require that a value of r of about six be chosen. Thus the moment of inertia of the viscous damper should be about six times the moment of inertia of the motor and its load.

The ratio r of moments of inertia should always be as small as can be permitted by the stability requirements, in order to secure reasonable nonlinear operation of the servomechanism. If the servomechanism error should become very large (under synchronizing conditions, for example) the velocity of the servomotor will reach a high value in turning to its correct position. Since the maximum torque of the servomotor is limited by saturation in the controller and motor, an excessive transient time may be required to absorb the kinetic energy of the servomotor,

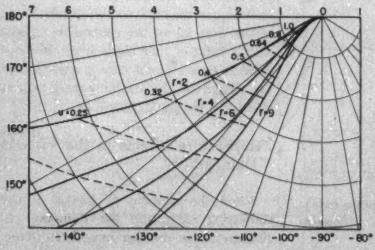


Figure 4 (left). Transfer function loci for the viscous-damper servomechanism

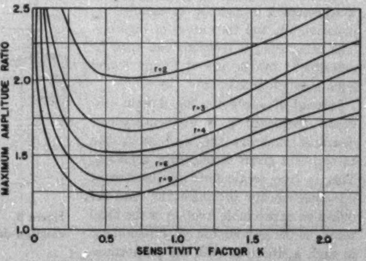
Figure 5 (right). Maximum amplitude ratio as a function of sensitivity factor for the viscous-damper servomechanism



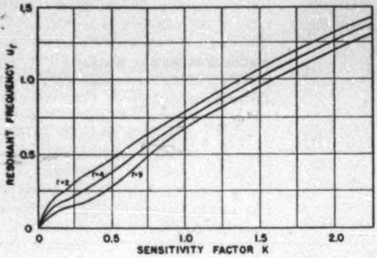


Figure 6 (left). Resonant frequency as a function of sensitivity factor for the viscous - damper servomechanism

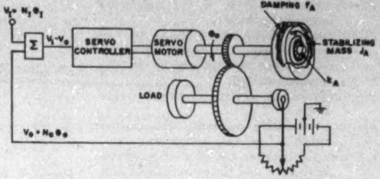

Figure 7 (right). Servomechanism stabilized by a spring-coupled damper

damper, and load. This transient time may be reduced by minimizing the total moment of inertia of the system. The system moment of inertia can be minimized by proper design of the servomotor and load, and by choosing the ratio r as small as is consistent with the desired margin of stability.

The resonant frequency of the instrument servomechanism also can be obtained from the loci of Figure 4 by the same graphical construction referred to before. The resonant frequency is the frequency at which the maximum amplitude occurs and is approximately equal to the system natural frequency, which is the frequency at which transients damp out. In Figure 6 is plotted the value of u_r at which resonance occurs as a function of the sensitivity factor. The resonant frequency ω_r, for a particular case, can be found from Figure 6 and the application of equation 10a.

$$\omega_r = u_r/\tau_d \tag{10a}$$

The curves of Figure 5 show that if the moment of inertia ratio r is six and the sensitivity factor K can be held at about six-tenths, the stability margin will be satisfactory. An additional system characteristic must be chosen in order that the system design may be completed. The characteristic commonly specified is either the system resonant frequency or the ratio of the motor torque to the error. If the resonant frequency is prescribed, the time constant τ_d can be determined by equation 10a and the curves of Figure 6. The other system relations can then be determined by the use of Figure 5 and equations 11 and 13.

Instead of specifying the system resonant frequency it is frequently more desirable to design the servomechanism to realize a given torque-error constant. This is true particularly of instrument servomechanisms in which the load requires an appreciable fraction of the total torque of the servomotor. It is important in such a situation that the proportionality constant relating the motor torque to system error be sufficiently large that the error caused by the load torque is limited to a tolerable value. If the magnitude of the load torque is known and the allowable error prescribed, the system torque-error constant can be calculated. The torque-error constant is the product k_cN_o appearing in equation 13, the expression for the system sensitivity factor K. Since the value of K may be selected from the curves of Figure 5, the ratio τ_d^2/J_m may be calculated, and the necessary value of the damping coefficient f_A, can be chosen once J_m, the combined moment of inertia of the motor and its load is known.

It is interesting to note that, according to the relations that have been presented here, both the resonant frequency and the torque-error constant can be increased indefinitely by making the damping constant, f_A, larger and larger. This anomaly is caused by the assumption that the time lag τ_c, is zero; that is, the torque developed by the servomotor has been assumed to be instantaneously proportional to the servo error. Actually the time lag τ_c is very small, and provided that it does not exceed a determinable value, it may be neglected and the preceding relations are valid.

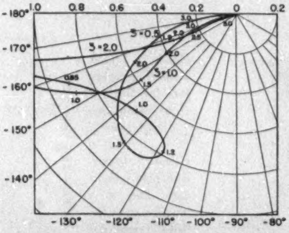

Figure 8. Transfer function loci for the spring-coupled-damper servomechanism. Moment-of-inertia ratio $r=1$

The lag τ_c appears in the lag factor $1/1 + j\,\tau_c/\tau_d u$ in equation 12. A safe criterion is to require the controller time lag τ_c, to be equal to or less than that value for which the lag factor introduces about five degrees phase shift in the transfer function at the system resonant frequency ω_r (reference 1, page 128). If the lag τ_c satisfies this requirement, the locus of the transfer function including the time lag term is essentially the same for important frequencies as the locus with the lag equal to zero. The criterion is expressed in equation form

$$\frac{\tau_c}{\tau_d}u_r \leq 0.1 \tag{15}$$

Since $u_r = \tau_d\omega_r$

$$\tau_c \leq \frac{0.1}{\omega_r} \tag{16}$$

If the time lag τ_c, is less than the above value it can be safely neglected provided the system without lag is adjusted to have a reasonable margin of stability. It is generally possible for the time lag τ_c to be as large as $0.2/\omega_r$ without seriously affecting the system response. If τ_c is larger than $0.2/\omega_r$, the effect of the lag should be determined by plotting the locus of the transfer function with the lag included.

The allowable time lag as determined from the preceding relations is small for a high-performance instrument servomechanism. For example, if a servo with a resonant frequency of five cycles per second is desired, the time lag of the controller should be less than about three milliseconds. If the time lag is more than twice this figure, appreciable deterioration in performance will occur, and the performance cannot be predicted without including in the analysis the specific value of the time lag of the controller. While such a value of time lag is small, it is not difficult to achieve if care is exercised in the design of the coupling and output circuits in the servo controller.

Temperature Effects in the Viscous Damper

When the moment of inertia of the stabilizing mass and the damping coefficient of the damper have been deter-

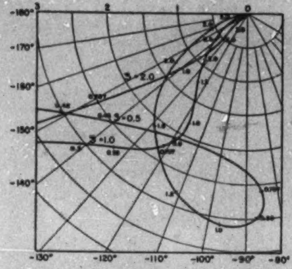

Figure 9. Transfer function loci for the spring-coupled-damper servomechanism. Moment-of-inertia ratio $r=4$

mined the mechanical design of the damper may be carried through. A damping medium must be chosen and while electromagnetic damping has the advantage of being independent of temperature the moment of inertia of the elements necessary to obtain a given value of the damping is excessive. Hydraulic fluids are available that provide high viscosity; unfortunately, the viscosity of the best of these fluids is by no means independent of temperature. There is no problem, of course, if the range of the operating temperature is small, since the viscosity of the oil and dimensions of the damper can be chosen to give almost any practical damping coefficient for a reasonable operating temperature. However, most military applications and some industrial applications require operation over a relatively large temperature range. For such applications the design of the damper is determined by the temperature requirements.

An example illustrates the importance of the temperature effect. The viscosity of a fluid (Dow Corning, type 200 Silicone fluid) with an unusually good temperature-viscosity characteristic varies by a factor of approximately three between a temperature of 35 and 130 degrees Fahrenheit. The damping coefficient f_A varies directly as the viscosity of the fluid, and the sensitivity factor K varies inversely as the square of the damping coefficient. (See equations 11 and 13.) If a servo using this fluid as a damping means must operate over this range of temperatures the damper design must provide for a nine-fold variation in K. Figure 5 indicates the effect of such a variation upon the maximum amplitude ratio. If the moment-of-inertia ratio is six or larger, this variation in K may be tolerable. For smaller values of moment-of-inertia ratio the maximum amplitude ratio at portions of the temperature range would normally be considered excessive. The larger the value of the moment-of-inertia ratio r, the wider can be the operating temperature range. Many military applications, however, require such a large range of operating temperature, as to exclude the possibility of employing a servomechanism stabilized with a viscous damper.

Design of a Spring-Coupled-Damper-Stabilized Servomechanism

The second type of load compensating element considered in detail is the spring-coupled damper. This device, shown schematically in Figure 2, operates in a substantially different manner than the viscous damper, and while somewhat more complex provides certain real advantages.

The block diagram of an instrument servo employing a spring-coupled damper for stabilization is shown in Figure 7. The differential equations of the system are as follows

$$m=J_m\frac{d^2\theta_o}{dt^2}+f_A\left(\frac{d\theta_o}{dt}-\frac{d\theta_A}{dt}\right)+k_A(\theta_o-\theta_A) \tag{17}$$

$$f_A\left(\frac{d\theta_o}{dt}-\frac{d\theta_A}{dt}\right)+k_A(\theta_o-\theta_A)=J_A\frac{d^2\theta_A}{dt^2} \tag{18}$$

$$m+\tau_c\frac{dm}{dt}=k_c(N_I\theta_I-N_o\theta_o) \tag{19}$$

in which k_A = spring constant of the spring coupling the damping mass to the servomotor and the other terms are defined following equation 6.

The sinusoidal relations equivalent to equations 17, 18 and 19 are

$$M=J_m(j\omega)^2\Theta_o+(\Theta_o-\Theta_A)(j\omega f_A+k_A) \tag{17a}$$

$$(\Theta_o-\Theta_A)(j\omega f_A+k_A)=J_A(j\omega)^2\Theta_A \tag{18a}$$

$$M(1+j\omega\tau_c)=k_c(N_I\Theta_I-N_o\Theta_o) \tag{19a}$$

The terms in these equations have been defined following equation 6a. The preceding equations may be solved algebraically and the system transfer function determined. If the frequency variable is transformed by

$$\frac{\omega}{\omega_0}=u \tag{20}$$

where

$$\omega_0^2=k_A/J_m \tag{21}$$

the transfer function can be written as follows

$$KG(ju)=\frac{k_cN_o}{k_A(1+r)}\,\frac{-ru^2+2j\zeta u+1}{-u^2\left(\dfrac{-u^2r}{1+r}+2j\zeta u+1\right)}\times\frac{1}{1+j\tau_c\omega_0u} \tag{22}$$

In equation 22

$$\zeta^2=\frac{f_A^2}{4k_AJ_m} \tag{23}$$

and the other terms have been defined in earlier parts of the paper.

The form of equation 22 emphasizes the fact that the sensitivity factor is

$$K=\frac{k_cN_o}{k_A(1+r)} \tag{24}$$

and the frequency dependent portion of the transfer function is given by

$$G(ju)=\frac{-ru^2+2j\zeta u+1}{-u^2\left(\dfrac{-u^2r}{1+r}+2j\zeta u+1\right)}\,\frac{1}{1+j\tau_c\omega_0u} \tag{25}$$

Reviewing for a moment the case of the viscous damper, the steps in the design study were first, the choice of the ratio r

(somewhat arbitrarily, initially) and plotting the corresponding transfer function locus; second, the determination from the locus of the maximum value of sensitivity K, consistent with the specified maximum amplitude ratio; and, third, repetition of the procedure for a range of values of r and comparison of the results.

The study of the spring-coupled damper is made similarly but is more lengthy because of the additional parameter, ζ, at the engineer's disposal.

Again it is expedient to neglect at first the controller time lag. After results have been obtained with zero controller lag, the upper limit of lag for which the results are valid can be determined. The steps in the design study are first, choose judiciously, if possible, the ratio r, and plot for a range of values of damping ratio ζ, the corresponding loci; second, determine from each locus the maximum value of the sensitivity, K, consistent with the permissible maximum amplitude ratio; third, choose as optimum that value of ζ that permits K to be maximum; and fourth, repeat the procedure for other values of r and compare the results. The optimum sensitivity K, the maximum amplitude ratio, and the resonant frequency are all determined by the graphical construction employed in the study of the viscous damper.

The loci for two values of the moment-of-inertia ratio r are illustrated in Figures 8 and 9. In each figure loci are plotted for several values of the damping ratio ζ. A range of values of r was investigated and the results of the study are summarized in Figure 10. A maximum amplitude ratio as low as four-thirds can not be obtained if the ratio r is less than about three. For r less than three, therefore, the optimum damping ratio ζ and the optimum sensitivity factor K, are chosen to minimize the maximum amplitude ratio. If the moment-of-inertia ratio r is larger than three, the damping ratio can be so selected that the maximum amplitude ratio can be less than four-thirds. Since in general there is no need for a larger stability margin the damping ratio when r is greater than three is chosen to permit the maximum sensitivity factor will not produce a peak amplitude response greater than four-thirds. For this reason the curve of M in Figure 10 is constant for r greater than three.

The resonant frequency that accompanies the choice of damping ratio ζ, and sensitivity factor K, is also plotted in Figure 10.

It is interesting to compare the results presented in Figure 10 for the spring-coupled damper and in Figure 5 for the viscous damper. For the viscous damper, the moment-of-inertia ratio must be at least six in order that the peak amplitude response be no larger than four-thirds. For the spring-coupled damper, however, the moment-of-inertia ratio need be only three to achieve the same result. Such a reduction in moment-of-inertia results in a real improvement in the synchronizing properties of the servomechanism.

The effect of temperature variation on the characteristics of the spring-coupled damper servomechanism is indicated by Figure 11, in which is plotted the maximum amplitude ratio as a function of the damping ratio ζ, for a moment-of-inertia ratio of four and several values of system sensitivity. The damping ratio ζ varies directly with the damping coefficient f_A, and therefore directly with the fluid viscosity. If the viscosity varies by a factor of three, as in the example considered earlier where the temperature ranged between 35 and 130 degrees Fahrenheit, the value of ζ will vary by three. The variation in the maximum amplitude ratio depends not only upon the variation in ζ but also upon its value at a particular temperature and the choice of sensitivity factor, K. Unlike the viscous damper, the sensitivity K, for the spring-coupled damper is independent of the damping coefficient. For a temperature range of 35–130 degrees Fahrenheit, an approximately optimum result is secured by choosing a sensitivity factor of 0.8 and a minimum ζ of 0.54. The maximum amplitude ratio is then the same at both ends of the temperature range and equal to 1.54. It is interesting to note that to limit the variation in the maximum amplitude ratio to this value for the viscous damper, a moment-of-inertia ratio of about 7.5 is required.

The criterion for the maximum permissible controller lag τ_c is the same as for the viscous damper. The term in which τ_c appears (see equation 22) should not introduce more than about five degrees phase shift at the system resonant frequency into the transfer function. This requirement is met provided

$$\tau_c \le \frac{0.1}{\omega_r}$$

where ω_r is the system resonant frequency expressed in radians per second.

It is revealing to contrast the optimum design of a spring-coupled damper for stabilizing a servomechanism with the design of a similar damper used as a vibration absorber on a rotating machine. In the latter case it is common to use a moment-of-inertia ratio of not more than one-fourth. Such a design, used in a servomechanism, would lead to a maximum amplitude ratio of at least three which today is considered entirely unsatisfactory. The difference in design arises from the difference in operation between open- and closed-cycled systems.

Example of an Instrument Servomechanism with Spring-Coupled Damper

During the last war there was a military requirement for an instrument servomechanism of good performance, minimum service requirements, and characteristics relatively independent of supply voltage, supply frequency, and temperature. Several types of instrument servomechanisms stabilized with spring-coupled dampers and employing induction motors as servomotors were developed in the servomechanisms laboratory of the Massachusetts Institute of Technology to meet these requirements. Their principal advantages are listed below.

Performance. These servomechanisms had an amplitude response essentially flat to 12 cycles per second. The performance was satisfactory for changes in the supply voltage and frequency of as much as 15 per cent. Some units were designed so that their performance essentially was unaltered for a change in operating temperature of 100 degrees Fahrenheit, and not seriously altered for a change in operating temperature of 150 degrees Fahrenheit.

Service Requirements. The induction motor is an ideal servomotor from the service standpoint. There are no brushes to wear out, and with conservative design the bearings and windings have an almost unlimited life. The spring-coupled damper employed was a sealed unit and required no attention. The amplifier controlling the servomotor contained no circuits requiring adjustment and included only one control, the gain control which was locked after initial adjustment. Since the amplifier was a proportional a-c amplifier, it required no special servicing techniques.

A diagram of one such unit is given in Figure 12. This servomechanism was used as a remote-position indicator and drove a relatively heavy mechanism.

The servomotor is a 4-pole, 60-cycle-per-second induction motor designed for a low moment of inertia of the rotor and a stalled torque of about four ounce inches. The data transmission system comprised two synchros, one geared to the servomotor, and the second remotely located. The electrical signal developed by the synchro coupled to the servo and supplied to the servo controller is proportional to the sine of the error of the relative position of the two synchros. The servo controller is a three-tube a-c amplifier with a power supply comprising a full-wave rectifier with capacitor filtering. The amplifier output is supplied to the control field of the induction motor, the second or reference field of which is connected to the a-c line through a phasing capacitor.

The induction motor has shafts extending from both ends of the rotor. One shaft couples the motor to the receiver synchro and load by means of a 100:1 gear reduction. The second shaft carries the spring-coupled damper. The servomotor and damper is shown in Figure 13. The damper housing is made of magnesium to minimize its moment of inertia, and completely encloses the damper in order to prevent leakage, eliminate dirt, and so forth. The damper moment of inertia is made of a lead alloy, and the housing is filled with a damping fluid with a viscosity of about 500 centistokes at room temperature.

The principal specification for this servomechanism was that it have a high torque-error constant, and this particular requirement determined the system design. It was desirable that the torque-error constant be about 0.2 ounce-inch per degree at the motor shaft, and this specification was met satisfactorily by the servo. This particular unit was required to operate over only a moderately wide temperature range and therefore a moment-of-inertia ratio r of three was chosen. The damper spring was selected to provide the specified torque-error constant, and since the moment of inertia of the motor rotor, damper housing, and load was about 0.1 ounce-inch squared, the natural frequency of the servomechanism was about 15 cycles per second. The time lag of the controller was kept at about one millisecond or less.

The servomechanism was tested by determining its transient response to certain test inputs. Three of the resulting records are given in Figure 14. The measurements were made by recording the receiver synchro voltage which is proportional to the servo error, except for inaccuracies in the data transmission system itself. In this type of test the data transmission errors should not be charged against the servomechanism. The test inputs were suddenly applied constant rotations of the transmitter synchro.

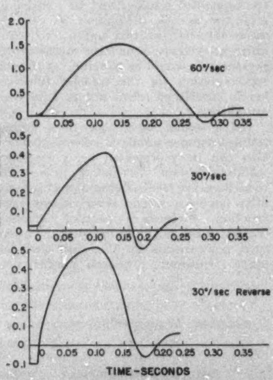

Figure 14. Transient responses of spring-coupled-damper servomechanism

Records are given of the servo response to velocity inputs of the transmitter synchro of 30 degrees per second, 60 degrees per second and a sudden reversal from 30 degrees per second in one direction to an equal velocity in the reverse direction. In all cases the transient has decayed in three-tenths second or less.

Conclusions

Load compensation of servomechanisms is a desirable method of stabilization under favorable circumstances. Compensation of certain types of instrument servomechanisms by either a viscous damper or a spring-coupled damper is effective. The spring-coupled damper is superior in that, for equal results it employs only about one-half the stabilizing moment of inertia required in the viscous damper.

The band width of instrument servomechanisms stabilized in this fashion can be made almost indefinitely wide provided the time lag in the controller and motor is made sufficiently small. With improperly chosen components, however, the nonlinear operation of such servomechanisms may not be satisfactory because of the larger moment-of-inertia coupled to the servomotor. An instrument servomechanism stabilized with a spring-coupled damper has been proved by service. This unit has a natural frequency of about 15 cycles per second and a torque-error constant of about 0.2 ounce-inch per degree measured at the servomotor shaft.

Discussion

Eric R. Behn (Control Instrument Company, Brooklyn, N. Y.): Hall refers to a common figure of merit generally applied to servomechanisms, namely, the maximum amplitude response ratio should be not greater than four-thirds of its zero frequency value. In this connection, where the resonant frequency of an instrument servomechanism is high, say 15 cycles per second, it may present an interesting departure from this usually accepted design criteria. In the frequency analysis as applied in the laboratory, it is usual to adjust the amplitude of the sinusoidal input to be larger than any accumulated backlash. Such an analysis might show a maximum amplitude response greater than four-thirds of its zero frequency value, yet the servomechanism would not be necessarily unstable because the amplitude of a 15-cycle-per-second component in the input data is usually quite small and may readily be less than the lost motion in a gear train or linkage.

The limitation of the maximum amplitude response to four-thirds is still a good design figure of merit. It is merely suggested that where the natural frequency is greater than ten cycles per second, a careful analysis be made of the probable input data and component design before a design is rejected. The writer has designed and built a servomechanism with a natural frequency of 20 cycles per second, which is quite stable even though the maximum amplitude response is three times its zero frequency value.

W. M. Pease (Massachusetts Institute of Technology, Cambridge, Mass.): It is interesting to consider that damper-stabilization may be treated as a form of feedback compensation. The feed-back link consists of a device sensitive to rotation of the output shaft which produces torque acting in opposition to the electrically produced air-gap torque in the servomotor. Thus, the air-gap torque produced as a result of servomechanism error is degenerated through feedback as a function of the servomechanism output. When this feed-back concept is expressed in the form of a block diagram, similarities between damper-stabilized servomechanisms and feed-back stabilized servomechanisms can be recognized.

For the viscous-damper-stabilized servomechanism, Hall's basic equations lead to a feed-back representation which is identical with a case treated by Harris,[1] in which a servomechanism was stabilized by tachometric feedback through a simple high-pass filter. Since both Hall and Harris give numerical solutions for their systems, it is interesting to compare the results. This is done in Table I of the discussion.

The equation expressing the system transfer function as derived by Hall is identical with a generalized solution of Herr and Gerst[2] if secondary time lags are neglected. The results for this case are also given in Table I. The results have been reduced to the form of Hall's solutions to make comparison simple. Note that the parameter r, chosen nearly identically by the three authors, represents ratio of inertias in Hall's case, feed-back sensitivity in Harris' case and the ratio of time constants in the Herr-Gerst case. A similar divergence of physical meaning applies to other parameters. For the adjustments indicated, system sensitivity may have two values based on the same criterion of peak amplitude response. Hall indicates both values, but selects the larger of the two and, at the same time, permits a relatively small secondary delay. Harris, on the other hand, selects the smaller of the two and permits a relatively large secondary delay. Hall's choice of sensitivity seems to be based on providing the least sensitivity to variations in viscosity of the damper fluid, while Harris' selection of sensitivity seems to be based on permitting the largest possible secondary delay. Herr and Gerst chose the value of sensitivity for which $M_p = 1.25$ at only one frequency. This seems to correspond to Hall's selection.

Table I

	Parameter Ratio r	System Sensitivity, Nondimensionalized K_1	Permissible Maximum Secondary Time Lag, Nondimensionalized
Hall	9	0.37	0.02
		0.78	0.05
Harris	10	0.36	0.44
Herr-Gerst	9.6	0.76	0

Anyone attempting a comparison such as that in Table I will observe a weakness in the manner in which transfer functions for servomechanisms are represented. All three cases were nondimensionalized, but on different bases, and the similarity between the numerical results could be noted only after considerable calculation. Where the same transfer function applies to many different systems, a uniform mathematical presentation would be of value. A suitable representation for the transfer functions herein considered seems not to have been established.

Hall's second case, that of a spring-coupled-damper-stabilized servomechanism, also can be represented as a feed-back stabilized system. In this case, it is similar to tachometric feedback through a high-pass filter having a second order characteristic function. Because a parallel numerical treatment has not been found in the literature, comparisons for this case were not made. However, a general parallel does suggest itself. As the addition of the spring is beneficial to the damper-stabilized servomechanism, so is the use of a high-pass filter of second or higher order beneficial to the servomechanism stabilized by tachometric feedback.

2. The Analysis and an Optimum Synthesis of Linear Servomechanisms, Donald Herr, Irving Gerst. AIEE Transactions, volume 66, 1947, pages 959–70.

Albert C. Hall: Behn, in commenting upon the design criterion that limits the maximum amplitude response of a servomechanism to approximately four-thirds has touched upon a very interesting point, namely, the determination of the margin of stability required in a closed-cycle system. The margin of stability is fixed generally by the following two considerations: First, the factor of safety required in order that maladjustments, component aging, and so forth will not produce actual instability; and second, the requirement that the servomechanism not magnify unduly the energy appearing in any particular frequency band of the signal. The determination of the maximum allowable amplitude ratio from either standpoint is a function among other things, of the type of servomechanism, the particular signals it must follow, and the service in which it may operate. Unusual conditions can affect appreciably the permissible maximum amplitude ratio. For example, if a servomechanism has a natural frequency of 20 cycles per second, but is subjected to input signal with negligible energy beyond two cycles per second, a much higher amplitude peak than four-thirds is permissible, provided component aging and maladjustments do not cause problems.

In general, however, servomechanisms are not designed with band widths ten times that required, and therefore appreciable signal energy does exist at all frequencies within the servo band pass. In addition, maladjustments are realistic service problems. For the majority of practical cases, therefore, a value of the maximum amplitude ratio of four-thirds to three-halves seems to give satisfactory results.

The comparison, provided by Pease, of the damper-stabilized servomechanism and the feed-back stabilized servomechanism is significant. It could have been extended as well to servomechanisms stabilized by cascade compensation. The agreement is illustrative of the fact that for the same system performance the transfer functions of either the cascade compensated, the feed-back compensated, or the load compensated servos will be the same. After proper transformation the design parameters of one system may be employed to determine parameters of either of the other two.

Graphical Determination of Transfer Function Loci for Servomechanism Components and Systems

C. H. THOMAS
ASSOCIATE AIEE

E. C. EASTON
MEMBER AIEE

IN the designing of a linearly operating control system it is desirable to determine for the uncompensated system the variation with frequency of amplitude and phase of the transfer function. As shown by a number of authors, this knowledge enables the designer to ascertain stability, and to synthesize compensating devices for improving the performance of the completed system. If the system can be described quantitatively, the transfer function locus may be calculated. In some systems it is possible to obtain the transfer function locus experimentally by introducing appropriate sinusoidal signals and measuring relative output and input amplitudes and phase. On the other hand, systems may be envisioned where both numerical mathematical representation and sinusoidal measurements are not feasible. It is the purpose of this paper to suggest a method for determining either the open- or closed-loop relative amplitude and phase diagrams from a single transient measurement. The input transient signal is not restricted in form particularly and may be of such nature that actual operating conditions of the system are duplicated approximately. Experimental results indicate the method to be practicable. The equations derived are applicable where the assumption of linearity and lumped parameters is reasonable.

Methods of Analysis

Laplacian Transform Equation

For generality a given open-cycle system, or isolated component of a more complex system, may be represented by a block as shown in Figure 1. The Laplacian transform equation relating input and output transforms is

$$F_o(s)=KG(s)F_i(s) \tag{1}$$

where $F_i(s)$ is the transform of the input signal $f_i(t)$, $F_o(s)$ is the transform of the output response $f_o(t)$, and $KG(s)$ is defined as the system transfer function.[1,2] The direct Laplace transforms of the input and output time functions are respectively

$$F_i(s)=\int_0^\infty f_i(t)e^{-st}dt \tag{2}$$

and

$$F_o(s)=\int_0^\infty f_o(t)e^{-st}dt \tag{3}$$

where $s=\sigma+j\omega$ and both σ and ω are real variables.[3] From equations 1, 2, and 3 there is obtained

$$KG(s)=\frac{\int_0^\infty f_o(t)e^{-st}dt}{\int_0^\infty f_i(t)e^{-st}dt} \tag{4}$$

Modifications of this expression, equation 4, for the transfer function are developed for special case applications in the following sections.

Bounded Transient Input Signal

Since it is desired to obtain the amplitude and phase of the transfer function $KG(j\omega)$ as a function of frequency, the complex variable s may be set equal to $j\omega$, and equation 4 becomes

$$KG(j\omega)=\frac{\int_0^\infty f_o(t)e^{-j\omega t}dt}{\int_0^\infty f_i(t)e^{-j\omega t}dt},$$

$$=\frac{\int_0^\infty f_o(t)\cos\omega t\,dt-j\int_0^\infty f_o(t)\sin\omega t\,dt}{\int_0^\infty f_i(t)\cos\omega t\,dt-j\int_0^\infty f_i(t)\sin\omega t\,dt} \tag{5}$$

Use of equation 5 requires the input signal and output response to be of such form that the integrals may be evaluated. This condition is realizable practically. The integrals may be evaluated by simple graphical procedures or by other convenient methods. It is necessary only to introduce into the system a bounded transient signal of more or less arbitrary form, taking simultaneous records of this signal and the system response. The duration time and maximum amplitude of the input signal should be so adjusted that the system is not overdriven or saturated. Furthermore if the duration time is made of the order of magnitude of the period of the highest frequency for which $KG(j\omega)$ is to be determined, graphical integration is much easier to perform. This is evident since over the finite interval of integration the number of positive and negative areas is reduced.

Step Function Input Signal

With a step function input the output response may be one of many possible forms depending on the nature of the particular system. For example the output voltage $e_o(t)$ as a result of a step input voltage $e_i(t)$ to a few simple electrical networks is sketched in Figures 2(a), (b), and (c). In Figure 2(d) is shown a sketch of the response of a second-order open-cycle servo system. In these examples, as well as many higher order systems, the steady-state component of the output response may be either zero, a constant, a linear function of time, or a constant

Transfer function

$$KG(j\omega)=\frac{1}{j\omega T+1}$$
$$=\frac{1}{\epsilon_i}\left[\epsilon_i+\omega\int^\infty(-\epsilon_i e^{-t/T})\sin\omega t\,dt+ j\omega\int_0^\infty(-\epsilon_i e^{-t/T})\cos\omega t\,dt\right]$$

(c). Differentiating type network

Time constant: $T=\dfrac{R_oRC}{R_o+R}$

Attenuation constant:

$\alpha=\dfrac{R_o+R}{R_o}$

Steady-state component of response

$\epsilon_{oc}(t)=k=\epsilon_i/\alpha$

Transient component of response

$\epsilon_{ot}(t=\dfrac{\alpha-1}{\alpha}\epsilon_i e^{-t/T}$

Total output response

$\epsilon_o(t=\dfrac{\epsilon_i}{\alpha}+\dfrac{\alpha-1}{\alpha}\epsilon_i e^{-T/t}$

Transfer function

$$KG(j\omega)=\frac{1}{\alpha}\frac{j\omega T\alpha+1}{j\omega T+1}$$
$$=\frac{1}{\epsilon_i}\left[\frac{\epsilon_i}{\alpha}+\omega\int^\infty\times\left(\frac{\alpha-1}{\alpha}\epsilon_i e^{-t/T}\right)\sin\omega t\,dt+ j\omega\int_0^\infty\left(\frac{\alpha-1}{\alpha}\epsilon_i e^{-t/T}\right)\cos\omega t\,dt\right]$$

(d). Second-order open-cycle servo system

Time constant, T; gain factor, K_a; steady-state component of response

$\theta_{oc}(t)=-k+mt$

Transient component of response

$\theta_{ot}(t)=ke^{-t/T}$

Total output response (angular position)

$\theta_o(t)=-k+mt+ke^{-t/T}$

Transfer function

$$KG(j\omega)=\frac{K_a}{j\omega(j\omega T+1)}$$
$$=\frac{1}{\epsilon_i}\left[(-k)+\omega\int^\infty ke^{-t/T}\times\sin\omega t\,dt-j\frac{m}{\omega}+j\omega\int_0^\infty ke^{-t/T}\cos\omega t\,dt\right]$$

where $\dfrac{k}{\epsilon_i}=K_aT$ and $\dfrac{m}{\epsilon_i}=K_a$

plus a linear function of time. Such a steady-state response may be expressed

$$_c(t)=k+mt \tag{6}$$

where k and m are constants, and t is the independent variable time. By superposition the total output response may be written as a sum of steady-state and transient components. Thus,

$$\begin{aligned}f_o(t)&=f_c(t)+f_t(t)\\&=k+mt+f_t(t)\end{aligned} \tag{7}$$

The direct Laplace transforms of step input ϵ_i and output $f_o(t)$ are respectively

$$F_i(s)=\int_0^\infty \epsilon_i e^{-st}dt=\frac{\epsilon_i}{s} \tag{8}$$

$$\begin{aligned}F_o(s)&=\int^\infty[k+mt+f_t(t)]e^{-st}dt\\&=\frac{k}{s}+\frac{m}{s^2}+\int_0^\infty f_t(t)e^{-st}dt\end{aligned} \tag{9}$$

Substituting equations 8 and 9 in 4 gives

$$KG(s)=\frac{1}{\epsilon_i}\left[k+\frac{m}{s}+s\int_0^\infty f_t(t)e^{-st}dt\right] \tag{10}$$

Setting $s=j\omega$ there is obtained

$$KG(j\omega)=\frac{1}{\epsilon_i}\left[k+\omega\int_0^\infty f_t(t)\sin\omega t\,dt- j\frac{m}{\omega}+j\omega\int_0^\infty f_t(t)\cos\omega t\,dt\right] \tag{11}$$

If the mathematical expression for the pure transient component $f_t(t)$ of the output response is uncertain, graphical integration as indicated by equation 11 yields the transfer function locus. Upon application of this expression to the responses illustrated in Figure 2, the transfer function loci shown are obtained.

Experimental Application

DESCRIPTION OF SYSTEM TESTED

For the purpose of testing the practicability of utilizing the relations derived in the preceding paragraphs a simple position control system was built. The schematic diagram of this system is shown in Figure 3. The principle components are as follows: selsyns for detection of position error, a demodulator for converting the 60-cycle error voltage to a d-c voltage, an electronic amplifier, an amplidyne, a d-c shunt motor, and a small d-c generator coupled directly to the motor shaft for the purpose of measuring motor speed. This setup was chosen for two predominant reasons, namely; (1) mathematical representation of the system is lengthy, since there are at least five time delays present, and (2) the transfer function locus is measurable directly and the calculated locus can be checked for accuracy.

DIRECT MEASUREMENT OF THE TRANSFER FUNCTION LOCUS

The schematic arrangement for the direct sinusoidal measurements is shown in Figure 4. The signal generator consists of two identical selsyns connected

together by a differential and driven through suitable gear reduction by a constant speed d-c motor. In order to obtain the required low frequency signals the 60-cycle carrier voltage is modulated as desired by adjustment of the motor speed. The relative phase of the input and reference signals is controlled by changing the angle between the two selsyns through the medium of the differential. Relative phase may be read from a calibrated dial. The modulated reference signal and tachometer voltages feed through the continuous calibrator to the vertical and horizontal amplifier circuits of the cathode-ray oscilloscope. These two sinusoidally varying voltages form a pattern on the oscilloscope screen. The relative phase of the reference signal voltage envelope and the system output tachometer voltage may be adjusted to zero by changing the relative position of the reference selsyn. The phase shift through the system is thus obtained. The continuous calibrator[4] periodically disconnects the inputs to the oscilloscope for a brief interval of time and feeds variable calibrating voltages independently to the vertical and horizontal input circuits. A bright spot of light appears on the oscilloscope screen simultaneously with the pattern which is being studied. By means of two potentiometers on the panel of the calibrator the spot can be moved to any position on the screen. Two voltmeters on the panel read respectively the horizontal and vertical positions of the spot. By proper positioning of the spot the magnitudes of the two voltages being compared can be determined simultaneously.

Figure 5(a) shows the experimental setup, and Figure 5(b) shows the control panel of the continuous calibrator and the screen of the cathode-ray oscilloscope. The figure traced on the screen (long persistence type of screen) is that obtained when the phase difference of the reference signal and system output is zero. For this illustration, the input signal was being modulated at a frequency of one cycle per second. The calibrating spot has been moved to the upper right-hand portion of the screen so that it may be seen clearly. During actual measurements, readings were taken with the spot positioned to each of the four corners of the "bow tie" figure.

Figure 6 is an oscillogram showing waveforms of input signal and system output. Note that the output oscillation

is displaced by a constant value from zero. This was produced by a small unbalance of the demodulator and was purposefully done in order to compel the servo motor to run continuously in one direction. This reduced undesirable variations in friction and enabled the pattern on the oscilloscope screen to remain practically stationary.

The transfer function locus $E_o(j\omega)/E_i(j\omega)$ measured directly is shown in Figure 7. It should be pointed out that this plot relating the amplitude and phase of output and input voltages is not in the form most convenient for synthesis studies. Usually for a system such as this the output angular position and input angular error are related to form a transfer function. It may be shown very simply that this open-loop transfer function is

$$\frac{\theta_o(j\omega)}{\theta_i(j\omega)}=\frac{K_1}{rK_tj\omega}\,\frac{E_o(j\omega)}{E_i(j\omega)} \tag{12}$$

where $\theta_o(i\omega)/\theta_i(j\omega)$ is the ratio of output shaft angular position to input angular error, K_1 is the selsyn sensitivity expressible in volts per radian, K_t is the tachometer constant in volts per radian per second, r is the gear ratio between the servomotor and output shaft, and $E_o(j\omega)/E_i(j\omega)$ is the locus plotted in Figure 7.

CALCULATIONS BASED ON MEASUREMENT OF TRANSIENT RESPONSE TO A BOUNDED-INPUT SIGNAL

With gain adjustments in the system unchanged and with the setup as indicated in Figure 4, the oscillogram shown in Figure 8 was obtained. The input signal, the envelope of which is of haphazard form, was produced by varying the selsyn excitation. Note that the input starts at zero and returns to zero. It may be observed that the output response (tachometer voltage which is directly proportional to motor speed) begins at an initial small value and returns to this same value. Again the demodulator was purposely unbalanced so as to cause the motor to run continuously, thus avoiding frictional effects which arise when starting from standstill.

These waveforms are suitable for the application of equation 5, where as indicated in Figure 8, the output response is

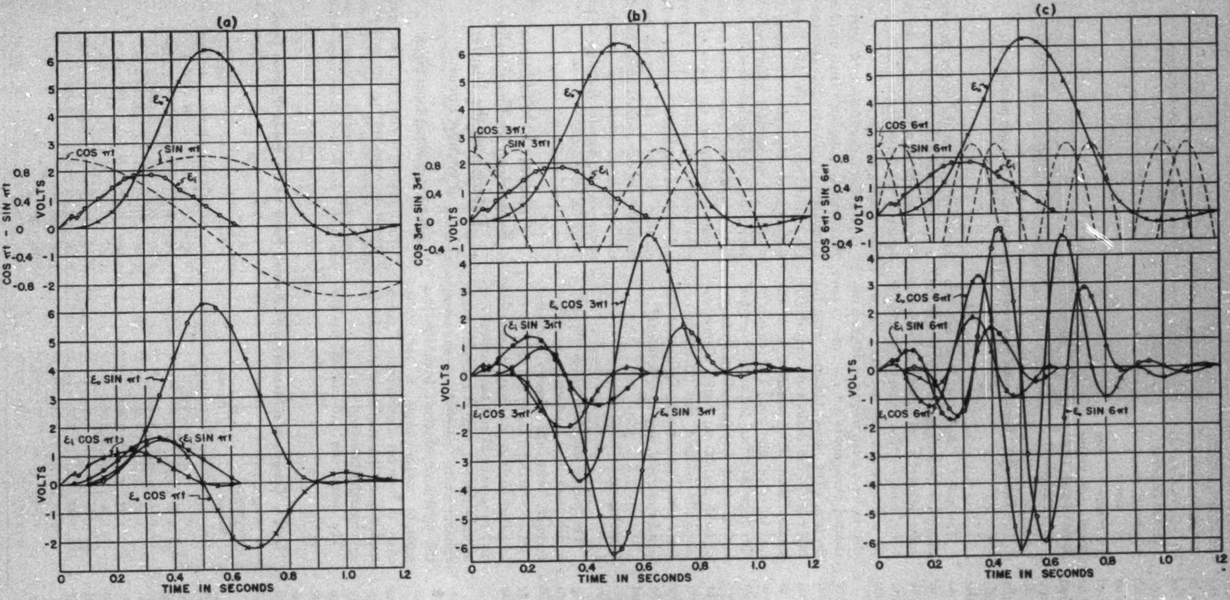
$$f_o(t)=\epsilon_t(t) \tag{13}$$

and the input signal is

$$f_i(t)=\epsilon_i(t) \tag{14}$$

The input signal $\epsilon_i(t)$ has been considered to be the envelope of the 60-cycle voltage fed to the demodulator. Such an assumption is felt to be justifiable since due to the action of the demodulator, the system in fact sees only this envelope.

In Figures 9(a), (b), and (c) is demonstrated the procedure used for the evaluation of the integrals contained in equation 5. The input signal envelope and the



(a). One-half cycle per second

$\int_0^\infty e_i \cos \pi t \, dt = 0.364$ volt-second

$\int_0^\infty e_i \sin \pi t \, dt = 0.520$ volt-second

$\int_0^\infty e_o \cos \pi t \, dt = -0.084$ volt-second

$\int_0^\infty e_o \sin \pi t \, dt = 2.252$ volt-second

$$KG(j\omega)\Big|_{f=0.5} = \frac{-0.084 - j2.252}{0.364 - j0.520} = 3.55\underline{/-37.10^\circ}$$

(b). One and one-half cycles per second

$\int_0^\infty e_i \cos 3\pi t \, dt = -0.292$ volt-second

$\int_0^\infty e_i \sin 3\pi t \, dt = 0.0744$ volt-second

$\int_0^\infty e_o \cos 3\pi t \, dt = 0.304$ volt-second

$\int_0^\infty e_o \sin 3\pi t \, dt = -0.856$ volt-second

$$KG(j\omega)\Big|_{f=1.5} = \frac{0.304 + j0.856}{-0.292 - j0.0744} = 3.02\underline{/-123.80^\circ}$$

(c). Three cycles per second

$\int_0^\infty e_i \cos 6\pi t \, dt = -0.007$ volt-second

$\int_0^\infty e_i \sin 6\pi t \, dt = 0.012$ volt-second

$\int_0^\infty e_o \cos 6\pi t \, dt = 0.014$ volt-second

$\int_0^\infty e_o \sin 6\pi t \, dt = -0.012$ volt-second

$$KG(j\omega)\Big|_{f=3} = \frac{0.014 + j0.012}{-0.007 - j0.012} = 1.32\underline{/-199.0^\circ}$$

Figure 9. Graphical evaluation of the integrals of equation 5

output response, as obtained from the oscillogram in Figure 8, are replotted in each of the examples. The evaluation of each integral, the net area under the appropriate curve, was accomplished with the aid of a planimeter. The points on the transfer function locus determined thusly are plotted in Figure 7. It may be observed in Table I that the measured phase shift and the calculated phase shift for a particular frequency check to within four degrees or less except for the highest frequency (3 cycles per second) where the discrepancy is about 13 degrees. The measured and calculated amplitudes check to within 6 per cent or less over most of the locus, except for the highest frequencies. At three cycles per second the amplitude discrepancy is about 45 per cent.

The discrepancy mentioned above possibly may be explained as follows. Referring to Figure 9(c) it may be seen that the input signal duration time is nearly equal to two periods of the 3-cycle per second wave, and that all net areas measured with the planimeter were very small. Chances for making a large error thus were fairly great. A good criteria for this system and other similar systems appears to be "the duration time of the arbitrary input signal should be adjusted to be not greater than one to one and one-half times the period of the highest frequency for which the transfer function locus is to be evaluated." The optimum duration time of the transient input would also depend upon the number and magnitude of the time delays in the particular system.

CALCULATIONS BASED ON MEASUREMENT OF TRANSIENT RESPONSES TO A STEP FUNCTION INPUT SIGNAL

With a step function input signal the oscillogram shown in Figure 10 was obtained. Again the system responds only to the envelope of the input signal, and to a reasonable approximation this may be considered to be a step function. Equation 11, therefore, is applicable. The transient component of the output response is

$$f_t(t)=\epsilon_t(t) \tag{15}$$

and the constant k is the final change in the tachometer voltage. Note that the constant m is zero.

The method of evaluating the two integrals in equation 11 is demonstrated in Figures 11(a), (b), and (c). The graphical integration was carried out with the aid of a planimeter as in the preceding example. The points calculated for this case are plotted in Figure 7.

A—Step function input (2.70 volts peak)
B—Servomotor speed response
C—Initial speed of motor
D—Steady-state speed due to the input signal (9.40 volts equivalent)

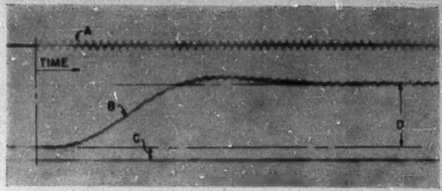


Figure 10. Oscillogram of servomotor speed response to a step function input

The points calculated from the two dissimilar measurements yield nearly the same locus for all practical purposes. Note, however, the frequency parameter for a given point does not check exactly, that is, for a given frequency the two calculated phase shifts differ by one to ten degrees. The phases obtained from the latter set of calculations are consistently smaller than those obtained from the first set of calculations. The reasons for this discrepancy are not entirely certain, but at least two contributing factors probably are, (1) the system is not linear as ideally assumed, and (2) changes in some of the parameters, mechanical friction for example, may have occurred.

Conclusion

The points calculated from the first measurement are in better agreement generally with the directly measured locus. For this reason and due to the fact that such an arbitrary input signal may be more easily realized practically, it appears the first type of transient measurement is to be preferred. In any event, the agreement obtained from the two separate measurements is sufficiently close to warrant further investigation toward using this technique as an aid in servomechanism design.

The amplitude attenuation of the measured locus at the higher frequency end relative to the calculated locus was due probably to a decrease in the gain factor of the demodulator in going from low to higher frequencies.

It is evident that if the time delays in the system are sufficiently large, graphical integration at the higher frequency end of the transfer function locus may be subject to intolerable errors. In some instances this undesirable feature may be avoided by breaking the system into two or more components, and by the methods described determine the locus of each component separately. The resulting loci may be combined by vector multiplication to obtain the over-all locus, providing the components are in cascade and there is no interaction effecting a change in the transfer function of the individual components.

Appendix I. Additional Expressions for Graphically Determining the Transfer Function Locus

Damped Exponential Input Signal

If it is possible to make the input signal a simple mathematical function, such as a damped exponential, the integrals in the denominator of equation 5 may be immediately determined and considerable

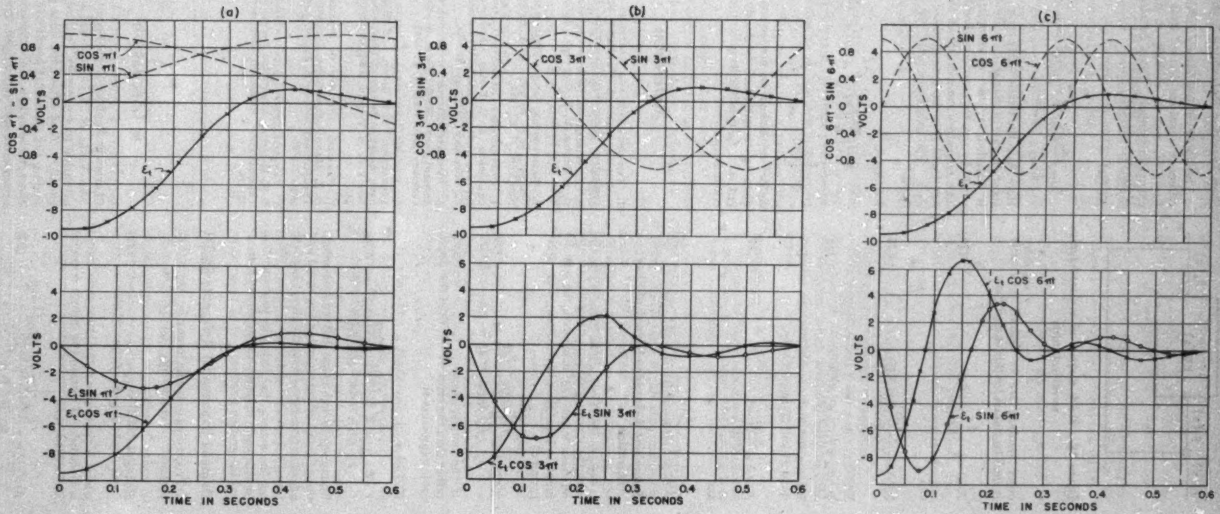
3.00	$0.90\underline{/-212.0^\circ}$	$0.96\underline{/-215.7^\circ}$	$1.32\underline{/-199.0^\circ}$



(a). One-half cycle per second

$\int_0^\infty \epsilon_t \sin \pi t\, dt = -0.448$ volt-second

$\int_0^\infty \epsilon_t \cos \pi t\, dt = -1.668$ volt-second

$$KG(j\omega)\Big|_{f=0.5} = \frac{1}{2.7}(9.40-0.448\pi-j1.668\pi) = 3.54\underline{/-33.3^\circ}$$

(b). One and one-half cycles per second

$\int_0^\infty \epsilon_t \sin 3\pi t\, dt = -1.380$ volt-second

$\int_0^\infty \epsilon_t \cos 3\pi t\, dt = -0.842$ volt-second

$$KG(j\omega)\Big|_{f=1.5} = \frac{1}{2.7}[9.40-(1.38)(3\pi) - j(0.842)(3\pi)] = 3.23\underline{/-114.5^\circ}$$

(c). Three cycles per second

$\int_0^\infty \epsilon_t \sin 6\pi t\, dt = -0.608$ volt-second

$\int_0^\infty \epsilon_t \cos 6\pi t\, dt = 0.080$ volt-second

$$KG(j\omega)\Big|_{f=3} = \frac{1}{2.7}[9.40-(0.608)(6\pi) + j(0.080)(6\pi)] = 0.960\underline{/-215.7^\circ}$$

Figure 11. Graphical evaluation of the integrals of equation 11

paper work saved thereby. Thus, if

$$f_i(t)=\epsilon_i e^{-bt} \tag{16}$$

then

$$KG(j\omega)=\frac{b+j\omega}{\epsilon_i}\left[\int_0^\infty f_o(t)\cos\omega t\,dt-i\int_0^\infty f_o(t)\sin\omega t\,dt\right] \tag{17}$$

The value of the damping factor b should be chosen with the view of making the graphical integration as simple as possible.

Step Sinusoidal Input Signal

For this case the input may be expressed

$$f_i(t)=\epsilon_i\cos(\lambda t+\alpha) \tag{18}$$

The total output response again may be written as a sum of steady-state and transient components. If the steady-state output is assumed to be of the same form as the input, then

$$f_c(t)=\epsilon_c\cos(\lambda t+\beta) \tag{19}$$

and

$${}_o(t)=\epsilon_c\cos(\lambda t+\beta)+f_t(t) \tag{20}$$

Taking the direct Laplace transforms of equations 18 and 20 and substituting in equation 4 there is obtained

$$KG(s)=\frac{\epsilon_c}{\epsilon_i}\frac{s\cos\beta-\lambda\sin\beta}{s\cos\alpha-\lambda\sin\alpha}+\frac{\lambda^2+s^2}{\epsilon_i(s\cos\alpha-\lambda\sin\alpha)}\int_0^\infty f_t(t)e^{-st}dt \tag{21}$$

Setting $s=j\omega$,

$$KG(j\omega)=\frac{\epsilon_c}{\epsilon_i}\frac{\lambda\sin\beta-j\omega\cos\beta}{\lambda\sin\alpha-j\omega\cos\alpha}+\frac{\lambda^2-\omega^2}{\epsilon_i(j\omega\cos\alpha-\lambda\sin\alpha)}\times\left[\int_0^\infty f_t(t)\cos\omega t\,dt-j\int_0^\infty f_t(t)\sin\omega t\,dt\right] \tag{22}$$

Again the transfer function locus may be found by graphical integration of the transient component of the measured response. Determination of the various quantities in equation 22 may become rather tedious, and in such a case this type of input signal may be undesirable. In the event the system is sufficiently simple, and a particular value of α may be found where no transient exists, the transfer function becomes

$$KG(j\omega)=\frac{\epsilon_c}{\epsilon_i}\frac{\lambda\sin\beta-j\omega\cos\beta}{\lambda\sin\alpha-j\omega\cos\alpha} \tag{23}$$

Appendix II. Determination of the Open-Loop Transfer Function From Transient Measurements on the Closed-Loop System

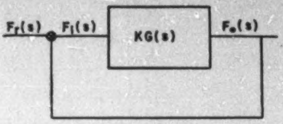


Figure 12. Block diagram of a closed-cycle servomechanism

One simple type of closed-cycle servomechanism may be represented as shown in Figure 12. The function $F_r(s)$ is the Laplace transform of the reference signal $f_r(t)$. The other symbols are as defined previously. It may be shown for this case[1,3] that

$$F_i(s)=\frac{1}{1+KG(s)}F_r(s) \tag{24}$$

and

$$F_o(s)=\frac{KG(s)}{1+KG(s)}F_r(s) \tag{25}$$

where

$$F_i(s)=F_r(s)-F_o(s) \tag{26}$$

Solving for the transfer function in equations 24 and 25 respectively,

$$KG(s)=\frac{F_r(s)}{F_i(s)}-1 \tag{27}$$

and

$$KG(s)=\frac{F_o(s)}{F_r(s)-F_o(s)} \tag{28}$$

Transient Reference Signal of Short Duration

For a transitory reference signal and with the input signal (error signal) $f_i(t)$ and reference signal $f_r(t)$ measured, the transfer function locus may be determined by application of

$$KG(j\omega)=\frac{\int_0^\infty f_r(t)e^{-j\omega t}dt}{\int_0^\infty f_i(t)e^{-j\omega t}dt}-1 \tag{29}$$

If the output response $f_o(t)$ is measured rather than the error signal, then the applicable expression is

$$KG(j\omega)=\frac{\int_0^\infty f_o(t)e^{-j\omega t}\,dt}{\int_0^\infty f_r(t)e^{-j\omega t}dt-\int_0^\infty f_o(t)e^{-j\omega t}dt} \tag{30}$$

Equations 29 and 30 are derived from equations 27 and 28 by replacing the signal and response transforms with the direct Laplace transform integral and setting $s=j\omega$. Writing the exponential terms in trigonometric form clearly indicates the necessary graphical integration process.

Damped Exponential Reference Signal

Proceeding as before it may be shown that for this type of reference signal $f_r(t)=\epsilon_r e^{-bt}$,

$$KG(j\omega)=\frac{\epsilon_r}{b+j\omega}\left[\frac{1}{\int_0^\infty f_i(t)e^{-j\omega t}dt}\right]-1 \tag{31}$$

which is applicable if the input error signal is recorded. If instead the output response is recorded, then

$$KG(j\omega)=\frac{(b+j\omega)(\int_0^\infty f_o(t)e^{-j\omega t}dt)}{\epsilon_r-(b+j\omega)(\int^\infty f_o(t)e^{-j\omega t}dt)} \tag{32}$$

Step Function Reference Signal

The applicable equations for this type of reference signal are derived from equations 8, 9, 27, and 28 making an appropriate change in symbols. Thus, for measurement of the error signal

$$KG(j\omega)=\frac{\epsilon_r}{k_i-j\frac{m_i}{\omega}+j\omega\int_0^\infty f_{it}(t)e^{-j\omega t}dt}-1 \tag{33}$$

Here, k_i is the steady-state error. The constant m_i, rate of change of steady-state error, is included for sake of completeness, but would be zero for most conceivable systems. The transitory component of the error is $f_{it}(t)$, and ϵ_r is the magnitude of the reference. For measurement of the output response

$$KG(j\omega)=\frac{k_o-j\frac{m_o}{\omega}+j\omega\int_0^\infty f_{ot}(t)e^{-j\omega t}dt}{\epsilon_r-\left[k_o-j\frac{m_o}{\omega}+j\omega\int_0^\infty f_{ot}(t)e^{-j\omega t}dt\right]} \tag{34}$$

As before, k_o and m_o are constants which describe the nature of the steady-state output, and $f_{ot}(t)$ is the transient component of the output.

Discussion

Charles F. Rehberg (New York University, New York, N. Y.): I should like to call attention to a paper by Bedford and Fredendall.[1] They attack the same problem of finding the sinusoidal amplitude and phase characteristics of a linear system from the experimentally determined transient response. Their method is essentially based on the Stieltjes integral representation

$$KG(s)=\int_0^\infty e^{-st}dA(t)$$

where $A(t)$ is the response of the system to unit step input. For purposes of numerical calculation, the integral may be replaced by an approximating sum, giving

$$KG(j\omega)\approx\sum e^{-j\omega t_k}[A(t_{k+1})-A(t_k)]$$

The latter may be evaluated by a geometric construction involving addition of vectors in the complex plane.

1. ANALYSIS, SYNTHESIS, AND EVALUATION OF THE TRANSIENT RESPONSE OF TELEVISION APPARATUS, Bedford, Fredendall. *Proceedings*, Institute of Radio Engineers (New York, N. Y.) volume 30, October 1942, page 440.

Paul Travers (Servomechanisms Laboratory, Massachusetts Institute of Technology Cambridge, Mass.): In those cases where the control system or element whose transfer function is to be determined cannot be disconnected from an operating system, the following procedure is of interest. This method is based upon the a priori assumption that the component to be tested is linear and that its input can be characterized by a stationary random process.[1]

$I(t)$ is the input to the component under consideration. Its output $o(t)$ is given by

$$o(t)=\int_0^\infty h(x)I(t-x)dx \tag{1}$$

where $h(t)$ is the normal impulse response of the component. Under normal operating conditions the integrated magnitude of $I(t)$ does not converge and therefore $h(t)$ may not be obtained by transform methods.

However, since $I(t)$ is a stationary random process the input-output cross-correlation function may be defined as

$$\varphi_{IO}(\tau)\overset{\Delta}{=}\lim_{T\to\infty}\frac{1}{2T}\int_{-T}^{T}I(t)o(t+\tau)dt \tag{2}$$

Equation 2 is expanded by the substitution of equation 1

$$\varphi_{IO}(\tau)=\lim_{T\to\infty}\frac{1}{2T}\int_{-T}^{T}I(t)\int_0^\infty h(x)\times I(t+\tau-x)dx\,dt \tag{3}$$

The order of integration is then changed to give:

$$\varphi_{IO}(\tau)=\int_0^\infty h(x)\lim_{T\to\infty}\frac{1}{2T}\int_{T}^{T}I(t)I\times(t+\tau-x)\,dt\,dx \tag{4}$$

The definition of the autocorrelation of the input is[1]

$$\varphi_{II}(\tau)\overset{\Delta}{=}\lim_{T\to\infty}\frac{1}{2T}\int_{-T}^{T}I(t)I(t+\tau)dt \tag{5}$$

Equation 4 then becomes a convolution similar to equation 1

$$\varphi_{IO}(\tau)=\int_0^\infty h(x)\varphi_{II}(\tau-x)dx \tag{6}$$

Since the integrated magnitudes of $\varphi_{IO}(\tau)$ and $\varphi_{II}(\tau)$ converge, $H(\omega)$ may be obtained by the Fourier transformation of equation 6

$$H(\omega)=\frac{\int_{-\infty}^{\infty}\varphi_{IO}(\tau)e^{-j\omega\tau}d\tau}{\int_{-\infty}^{\infty}\varphi_{II}(\tau)e^{-j\omega\tau}d\tau}\overset{\Delta}{=}\frac{\Phi_{IO}(\omega)}{\Phi_{II}(\omega)} \tag{7}$$

In a manner similar to the foregoing exposition the cross-correlation may be obtained for a system which has two inputs,

$$I(t)=J(t)+K(t) \tag{8}$$

The cross-correlation for one input and the output is

$$\varphi_{JO}(\tau)=\int_0^\infty h(x)[\varphi_{JJ}(\tau-x)+\varphi_{JK}(\tau-x)]dx \tag{9}$$

If it is known that $J(t)$ and $K(t)$ are unrelated then $\varphi_{JK}(\tau)$ becomes zero and equation 9 reduces to

$$\varphi_{JO}(\tau)=\int_0^\infty h(x)\varphi_{JJ}(\tau-x)dx \tag{10}$$

$H(\omega)$ is then determined by equation 7.

It is concluded that the transfer function, $H(\omega)$, may be determined in the presence of disturbances which are stationary random processes and which are unrelated to the input.

1. THEORY OF SERVOMECHANISMS, H. M. James, R. B. Nichols, R. S. Phillips. McGraw-Hill Book Company, New York, N. Y., 1947.

M. Yachter (M. W. Kellogg Company, Jersey City, N. J.): In this very interesting and important paper there is one weakness which, if not overcome, may reduce considerably the practical usefulness of the method studied by the authors. I refer to the numerical evaluation of the integral

$$I=j\omega\int_0^\infty f(t)e^{-j\omega t}dt=j\omega\int_0^\infty f(t)\times\cos\omega t\,dt+\omega\int_0^\infty f(t)\sin\omega t\,dt;\ j=\sqrt{-1}$$

where $f(t)$ is, as defined in the paper, the transient part of the output response to a step function (of constant amplitude or constant velocity) input so that

$$f(\infty)\to0$$

It is seen that if the transfer locus is to be calculated for, say, ten frequencies, 20 integrals must be evaluated. This is a very considerable amount of work.

Moreover, as ω increases the integrals oscillate more and more and their evaluation to any reasonable degree of accuracy becomes increasingly difficult. Indeed, the difficulty arises from the fact that in the limit $(\omega\to\infty)$ the integral I becomes indeterminate. For, one of the factors, $\omega\to\infty$ while the other factor

$$\int_0^\infty f(t)e^{-j\omega t}dt\to0$$

by the Riemann-Lebesgue lemma.[1] We see thus that the straight forward evaluation of the integrals for a reasonable range of frequencies is not practical. Now, this difficulty can be overcome by a very simple trick. The idea is merely to develop first the function $f(t)$ in some sort of a series

$$f(t)=\sum_0^\infty A_nU_n(t)$$

and such that the integrals

$$\int_0^\infty U_n(t)e^{-j\omega t}dt$$

can be integrated explicitly. Needless to add, the functions U_n should form an orthogonal set, so that the evaluation of the coefficients A_n is straightforward and convergence is, in general, assured (at least convergence "in the mean"). Now, there exist, of course, an infinite number of sets of orthogonal functions and the question is which of these should be used? On the basis of a one-degree of freedom system the following can be stated:

> If the (nondimensional) damping of the system is less than, say 0.7, then a Fourier series can be used to advantage. The number of terms required for good accuracy will be, at most, five (for $\zeta=0.7$).

If the damping of the system is greater than 0.7 then the orthogonal set of Laguerre polynomials[3], is generally more advantageous for convergence. Again, for $\zeta\geq0.7$, at most five terms may be necessary. Thus on the basis of a single degree of freedom system, $f(t)$ can be expressed in a series of at most five terms. The evaluation of the coefficients requires again the numerical evaluation of integrals essentially (for a Fourier series expansion exactly) of the same form as the integral I, but now only five (at most) integrals have to be evaluated instead of, say, 20 such evaluations. Once the coefficients have been found it is a very simple matter to calculate the transfer functions, and this in an exact manner. It may be added that the damping (and the natural frequency) can be estimated from the curves given in reference 3.

1. Suppose now that $\zeta\leq0.7$;

Let t_{ss} be the time at which $f(t)=\sim0$. That is $f(t)=0$ for $t\geq t_{ss}$.

Let now

$$\tau=\frac{\pi t}{t_{ss}};\ f(t)=F(\tau);\ \omega_{ss}=\frac{t_{ss}}{\pi}\omega \tag{1}$$

then

$$I=j\omega\int_0^{t_{ss}}f(t)e^{-j\omega\tau}dt$$
$$=j\omega_{ss}\int_0^{\pi}F(\tau)e^{-j\omega_{ss}t}d\tau;\qquad F(0)=f(0);\quad F(\pi)=0 \tag{2}$$

Write

$$F(\tau)=\sum_0^\infty A_n\cos n\tau$$

$$a_0=\frac{1}{\pi}\int_0^\pi F(\tau)d\tau;\ a_n=\frac{2}{\pi}\int_0^\pi F(\tau)\cos n\tau d\tau;\ (n=1,2,\ldots\infty) \tag{3}$$

Table I

ω	0	2.5	5	7.5	10	12.5	15	17.5	20
ω_{ss}	0	1/2	1	3/2	2	5/2	3	7/2	4
I	0 +0.j	0.833 +4.26j	3.867 +7.98j	9.075 +9.4j	13.9 +6.98j	15.6 +2.305j	13.1 −1.23j	11.17 −2.062j	9.64 −1.26j

Table II

ω	Author's Results	Fourier Series	Laguerre Series
π	$I=0.448\pi+1.668\pi j$	$0.44\pi+1.7\pi j$	$0.44\pi+1.667\pi j$
3π	$1.38\ (3\pi)$	$1.39\ (3\pi)$	$1.4\ (3\pi)$
	$+0.842\ (3\pi)j$	$+0.83\ (3\pi)j$	$+0.79\ (3\pi)j$
6π	$0.608\ (6\pi)$	$0.55\ (6\pi)$	$0.623\ (6\pi)$
	$-0.08\ (6\pi)j$	$-0.10\ (6\pi)j$	$-0.12\ (6\pi)j$

The values for $\omega=6\pi$ illustrate the difficulty of obtaining accurate results for higher frequencies.

Then we find

$$I=j\omega\int_0^\infty f(t)e^{-j\omega t}dt$$

$$=\sum_{n=0}^{\infty}\frac{a_n}{1-\left(\frac{n}{\omega_{ss}}\right)^2}[1-(-1)^n\cos\omega_{ss}\pi+ (-1)^n j\ \sin\ \omega_{ss}\pi] \qquad (4)$$

If $\omega_{ss}=m$, then the m^{th} term in the series becomes indeterminate, but this indeterminate form is easily evaluated to be

$$m^{th}\text{ term }=\frac{\pi}{2}\omega_{ss}a_m j \qquad (5)$$

If $\omega_{ss}=m$ or $\omega_{ss}=m+{}^1/_2$, where m is an integral number, the series (4) assumes a particularly simple form, thus

$$\omega_{ss}=m\begin{cases}I=2\sum\limits_{n=1,3\ldots}^{\infty}\dfrac{a_n}{1-\left(\dfrac{n}{m}\right)^2}+\dfrac{\pi}{2}ma_m j; & m\text{ even}\\ I=2\sum\limits_{n=0,2}^{\infty}\dfrac{a_n}{1-\left(\dfrac{n}{m}\right)^2}+\dfrac{\pi}{2}ma_m j; & m\text{ odd}\end{cases}$$

$$\omega_{ss}=m+{}^1/_2\begin{cases}I=\sum\limits_{n=0}^{\infty}a_n\dfrac{1+(-1)^n j}{1-\left(\dfrac{n}{(m+1/2)}\right)^2}; & m\text{ even}\\ I=\sum\limits_{n=0}^{\infty}a_n\dfrac{1-(-1)^n j}{1-\left(\dfrac{n}{m+1/2)}\right)^2}; & m\text{ odd}\end{cases} \qquad (6)$$

In general, evaluation of I for

$\omega_{ss}={}^1/_2,\ 1,\ {}^3/_2,\ \ldots\ 5$

is sufficient to determine the transfer function for the most practical range of frequencies. Thus it is seen that practically the main work consists in the evaluation of (at most) five integrals of the type

$\int_0^\pi F(\tau)\cos n\tau d\tau;\ (n=0,\ 1,\ \ldots\ 4)$, say

Limits

Suppose that

$\omega_{ss}=m\rightarrow\infty$

In general, it will be found (again say on the basis of a single degree of freedom) that

$$a_n\sim\frac{1}{n^2}$$

so that

$$\lim_{n\rightarrow m\rightarrow\infty}\frac{a_n}{1-\left(\frac{n}{m}\right)^2}\rightarrow 0$$

and in the limit

$\omega_{ss}=\infty$

we get

$$I=2(a_0+a_2+a_4+\ldots)=2(a_1+a_3+a_5+\ldots)=F(o)=f(o) \qquad (7)$$

That the above two expressions are equal to each other can be seen from the relations

$$a_0+a_1+a_2+\ldots=F(o);\qquad a_0-a_1+a_2-a_3+\ldots=0$$

Thus in the limit the imaginary part of I vanishes while the real part tends to the steady-state error. This will be the case if there is any inertia in the system.

2. Suppose now that $\zeta\geq 0.7$. It is now more advantageous to develop $f(t)$ into a series of Laguerre polynomials. The n^{th} normalized Laguerre polynomial is defined by

$$\varphi_n(\tau)=\frac{e^{-\tau/2}}{n!}Ln^{(\tau)};$$

$$\int_0^\infty\varphi_m(\tau)\varphi_n(\tau)d\tau=\begin{cases}0\text{ if }m\neq n\\ 1\text{ if }m=n\end{cases}$$

and

$$L_n(\tau)=e^{\tau}\frac{d^n}{d\tau^n}(\tau^n e^{-\tau})$$

$$=\sum_{k=0}^{n}(-1)^{n-k}\frac{[n(n-1)\ldots(n-k+1)]^2}{k!}\tau^{n-k}$$

so that,

$L_0=1;\ L_1=1-\tau;\ L_2=\tau^2-4\tau+2$ and so forth.

Let

$s=\xi+j\eta$

then, if $\xi<1/2$, we find

$$\int^\infty e^{s\tau}\varphi_n(\tau)d\tau=-\frac{1}{s-\frac{1}{2}}\left(\frac{s+\frac{1}{2}}{s-\frac{1}{2}}\right)^n \qquad (8)$$

The evaluation of equation 8 is somewhat lengthy, but is obtained by a continued integration by parts. Now let $F(\tau)$ be a function such that $F(\infty)=0$ and

$$\int_0^\infty[F^{(\tau)}]^2d\tau\neq\infty$$

which is surely true for transient response curves (that is the transient part $f(t)$); then it is possible to expand $F(\tau)$ in terms of the Laguerre polynomials

$$F(\tau)=\sum_0^\infty c_n\varphi_n(\tau);\ c_n=\int_0^\infty F(\tau)\varphi_n(\tau)d\tau \qquad (9)$$

with the assurance of convergence ("in the mean", see reference 2)

Hence we may write

$$\int_0^\infty F(\tau)e^{s\tau}d\tau=\sum_0^\infty c_n\int^\infty e^{s\tau}\varphi_n(\tau)d\tau$$

$$=-\sum_0^\infty\frac{c_n}{s-\frac{1}{2}}\left(\frac{s+\frac{1}{2}}{s-\frac{1}{2}}\right)^n$$

Let

$$A=\int_0^\infty f(t)e^{-st}dt;\ \tau=\alpha t;\ f(t)=F(\tau);\ \alpha>0; \qquad (10)$$

then,

$$A=\frac{1}{\alpha}\int^\infty F(\tau)e^{-\frac{s}{\alpha}\tau}d\tau$$

$$=\frac{1}{\alpha}\sum_0^\infty\frac{c_n}{\frac{1}{2}+\frac{s}{\alpha}}\left(\frac{\frac{s}{\alpha}-\frac{1}{2}}{\frac{s}{\alpha}+\frac{1}{2}}\right)^n \qquad (11)$$

12	0.002479	−0.0273	0.122	−0.2650	0.240

The problem now is what value to choose for α.

Of course, this choice can not influence the end results, but it can, and does, influence the convergence. Again, on the basis of a single degree of freedom system, it turns out that for optimum convergence one must choose $\alpha=2\omega_n$, where ω_n is the (approximate) natural frequency of the system (on a single degree of freedom basis). Let now

$$s=j\omega;\quad \omega_{ss}=\frac{\omega}{\omega_n};\quad \frac{s}{\alpha}=\frac{1}{2}j\omega_{ss} \tag{12}$$

then

$$A=\frac{1}{2\omega_n}\sum_0^\infty \frac{c_n}{\frac{1}{2}(1+j\omega_{ss})}\left(\frac{j\omega_{ss}-1}{j\omega_{ss}+1}\right)^n$$

and finally

$$I=s\int_0^\infty f(t)e^{-st}dt$$

$$=\frac{\omega_{ss}}{\sqrt{1+\omega_{ss}^2}}e^{j\psi}\sum_0^\infty(-1)^n c_n e^{jn\theta}$$

where

$$\psi=\tan^{-1}\left(\frac{1}{\omega_{ss}}\right);\quad \theta=\tan^{-1}\left(\frac{-2\omega_{ss}}{1-\omega_{ss}^2}\right);$$

$$0\leq\psi\leq\frac{\pi}{2};\quad -\pi\leq\theta\leq 0 \tag{13}$$

with

$$c_n=\int_0^\infty F(\tau)\varphi_n(\tau)d\tau;\quad \omega_{ss}=\frac{\omega}{\omega_n}$$

If $\zeta>1$, then one should choose $\omega_n=1/t_0$ where t_0 is the decay time.

It is seen that again I is expressed in the form of a Fourier series except that the coefficients c_n are those corresponding to the Laguerre polynomials, rather than the Fourier series.

For ease of computations it is better to write

$$\Phi_n(\omega_{ss})=\Phi_{n1}(\omega_{ss})+j\Phi_{n2}(\omega_{ss})=$$

$$\frac{\omega_{ss}}{\sqrt{1+\omega_{ss}^2}}e^{j(n\theta+\psi)} \tag{14}$$

so that,

$$I=\sum_{n=0}^\infty(-1)^n c_n\Phi_n(\omega_{ss}) \tag{15}$$

with tables for $\varphi_n(\tau)$ and $\Phi_n(\omega_{ss})$ it is just as easy to calculate I as in the case of the Fourier series. Such tables are added at the end of this discussion (Tables III and IV).

Finally, it may be added, that the same "technique" may perhaps be used to determine the transient response from a given frequency response or vice versa. However, because of lack of time the details have not as yet been worked out.

Numerical Examples

Consider the transient response curve e_t shown in Figure 11 of the paper under discussion. The damping factor and natural frequency are estimated to be

$$\zeta=0.56;\quad \omega_n=9.3\,\frac{\text{rad.}}{\text{sec.}};\quad t_{ss}=\frac{2\pi}{10}=0.628\text{ sec.}$$

According to what was said before, a Fourier series is more advantageous to use. However, the values of the integral I have been calculated by both methods.

Fourier Series

$$t_{ss}=\frac{\pi}{5};\quad \omega_{ss}=\frac{\omega}{5};$$

On the basis of 10 intervals, the following values for the Fourier coefficients have been found

$$a_0=2.66;\quad a_1=5.08;\quad a_2=2.22;\quad a_3=-0.262;\quad a_4=-0.201$$

The curve represented by the series of five terms follows the original quite closely except at the very end ($t=0.6$ sec.).

The values of I for a range of frequencies from $\omega=0$ to $\omega=20$ calculated from equation 6 is shown in Table I of the discussion.

Choose

$$\omega_n=10\,\frac{\text{rad.}}{\text{sec.}};\quad \omega_{ss}=\frac{\omega}{\omega_n}=\frac{\omega}{10}$$

for Laguerre expansion

The coefficients c_n have been calculated on the basis of 12 equal intervals, except that the first interval was subdivided into two half intervals, while the last two intervals have been taken as one. The values of the coefficients are:

$$c_0=15.24;\quad c_1=-5.707;\quad c_2=-3.55;\quad c_3=1.654;\quad c_4=1.264;$$

It is found that at $\tau=0$, these coefficients add up to 8.9 instead of to 9.42, which is the exact value. This shows that at least one more term is necessary in the series, and so for the value of $\zeta=0.56$, the Fourier series really gives better results as expected from theoretical considerations (on the basis of a single degree of freedom system).

Instead of calculating another term, the coefficients have been increased by weighted factors (inversely proportional to values of coefficients), so that the actual values used for calculating I are

$$c_0=15.26;\quad c_1=-5.66;\quad c_2=-3.47;\quad c_3=1.82;\quad c_4=1.48$$

The curve as represented by the Laguerre series with five terms follows the original curve less closely than the one given by the (finite) Fourier series, but is still a good approximation. With these coefficients the values of I have been calculated from equation 13 for $\omega=\pi$, 3π, 6π; for these frequencies the values of I have also been interpolated from Table I of the discussion. These values are compared with those obtained by the authors in Table II of the discussion.

D. D. Terwilliger (The Glenn L. Martin Company, Baltimore, Md.): The authors mention that some systems may be envisioned where mathematical or sinusoidal measurements are not feasible. No specific cases are given. I should like to mention a very common one in the hydraulic servo using a variable stroke pump and motor.

In this system under sinusoidal test the oil lines become supercharged so that the effect of oil compressibility appears as two springs, one on each side of the output inertia.

This will produce a natural frequency $\sqrt{2}$ times greater than if the oil in only one line is considered effective.

In transient tests no supercharging effect is present so that a lower natural frequency should be measured. Some laboratory work has been performed to substantiate this effect.

The application of the author's technique will simplify calculations and permit more complete information to be obtained on this very important part of a hydraulic servomechanism.

C. H. Thomas and E. C. Easton: The authors wish to acknowledge with gratitude the discussions of their paper by Travers, Rehberg, Yachter, and Terwilliger. The method of evaluating the infinite integral suggested by Yachter, appears to be much simpler than the method used by the authors and should prove of considerable use to those who desire to utilize this method of determining transfer function loci. The discussions seem to bring out the fact that the authors' method of utilizing the Laplace transformation for determining transfer function loci from transient measurements is more general than other methods which have been described in the literature. This method is not restricted by input signal form and is applicable for practically any type of applied signal.

Operating Characteristics of 2-Phase Servomotors

R. J. W. KOOPMAN
MEMBER AIEE

IN THIS paper differences are pointed out between conventional 2- phase induction motors and 2-phase servomotors, both as to construction and operating conditions. An important feature of the construction differences is that they determine whether or not the servomotor will operate single phase.

Performance of a servomotor having typical equivalent-circuit parameters is analyzed by means of symmetrical-component theory. The usual assumption made in control-system analyses of linearity of torque with control voltage is shown to be fairly accurate, but the assumption of linearity of speed with control voltage is shown to be very limited. Internal damping varies widely with voltage and speed.

Numerous interrelations between motor design and control system design are pointed out and should be of interest to those engaging in either of these fields. A contribution to induction motor theory is made in showing how design factors may be combined to prevent the production of positive torque from single phase regardless of the speed that may be given to the rotor. A contribution to servomechanism design is made in showing how to obtain the relationships between control voltage and torque, and also the slopes of the speed-versus-torque curves. These are needed to calculate the period and the damping respectively of a closed cycle system.

In the last few years small 2-phase induction servomotors[1] have become quite popular for use in control systems where relatively small torques are required.

The usual construction employs a stator with windings located 90 electrical space degrees apart and a rotor of fundamentally the squirrel-cage type. The stator windings may or may not be balanced electrically. Fundamentally then, this type of motor is similar to the more familiar split-phase and capacitor motors, or in the case of electrically balanced windings it is similar to the 2-phase squirrel-cage induction motor.

However, there are some differences in design details which make important differences in performance. Also the conditions under which the servomotors operate are different.

The applied voltages are rarely balanced, for to achieve control of torque and direction of rotation, the control-winding voltage may be varied from rated value in one sense through zero to rated value in the opposite sense while the voltage on the other winding is held constant.

When it is necessary to have a fast acting yet stable closed-cycle control system, it is highly desirable that the torque-to-inertia ratio of the servomotor have a large value. For this reason the rotor often consists only of a thin hollow cup of light conducting material in order to reduce inertia. The magnetic path is completed by means of a stationary cylinder of iron placed inside the rotor. There are thus two clearance air gaps. Motors made in this manner are frequently called "drag cup" motors.

This type of construction means that the exciting current as compared with that of motors of conventional design, is relatively large. Closed-cycle control systems normally require a servomotor with characteristics typical of high-rotor resistance. High-rotor resistance may combine with high exciting current to produce conditions which prevent the motor from developing any running torque when operating single phase regardless of speed. This is a very desirable characteristic for many control applications although it is an intolerable condition in split-phase or capacitor motors.

Manufacturers of 2-phase servomotors usually give the speed-torque curves of their various models for balanced-voltage operation, that is, rated voltage on each winding. These curves are usually drawn from the no-load to zero speed. In predicting accurately the performance of a closed-cycle control system, it is really essential to have the speed-torque curves for various values of voltage on the control winding. However, for purposes of simplification the following assumptions are usually made:

1. Torque at a given speed is directly proportional to the voltage on the control winding.
2. Speed at a given torque is directly proportional to control-winding voltage.
3. The slopes of the speed-torque curves are constant.

These assumptions are quite different from the expected performance of the usual polyphase squirrel-cage induction motor.

The purposes of this paper are to:

1. Show how well the foregoing assumptions fit a typical case and to establish analytical bases for them where possible;
2. Show how the speed-torque curve usually given by the manufacturer for balanced-voltage operation can be utilized to calculate the speed-torque curves for variable control-winding voltages;
3. Show how high exciting current and high-rotor resistance combine to produce single-phase characteristics peculiar to servomotors.

A literal analysis of the circuital relationships involved will be presented. This will apply equally well to conven-

Paper 49-81, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, New York, N. Y., January 31–February 4, 1949. Manuscript submitted July 21, 1948; made available for printing December 21, 1948.

R. J. W. Koopman is an associate professor at Washington University, St. Louis, Mo.

The author is indebted to Walter R. Evans for data concerning the closeness of correspondence between speed-torque curves calculated from the balanced-voltage curve in the manner suggested by the writer and curves obtained by experimental observation.

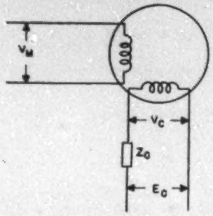

Figure 1. Servomotor circuits

tional 2-phase induction motors when operated under the conditions of unbalance common to servomotors. The results of applying the literal analysis to calculating the performance of a typical "drag cup" motor whose constants were determined by open-circuit and short-circuit tests in conjunction with consideration of actual performance will be presented in a group of curves. While no extensive laboratory checks were made on the performance curves, there is reasonably close general agreement between the theoretical results and those obtained in the laboratory and in practice. A more detailed appraisal of the expected correspondence between calculated and test results in general and a suggested method of measuring "constants" is given in Appendix III.

Analysis

SCOPE

This analysis is limited to control motors with electrically balanced windings 90 electrical space degrees displaced. It may be extended to motors in which the windings are electrically unbalanced by the argument followed in Appendix I. This paper deals mainly with the steady-state condition of operation. The transient condition also will be discussed, but it will be assumed that the electrical transients are fast and therefore negligible in comparison with the mechanical.

Two cases will be analyzed. In one case, the control voltage will be applied to the control winding through a resistance approximately equal to the average magnitude of the motor impedance. This corresponds in practice to supplying the winding from the plate circuit of a power amplifier tube matched to the motor winding through an impedance matching transformer. The second case will be that in which the control voltage is applied directly to the winding. This corresponds in practice to supplying the winding from a low-impedance generator, or the condition can be approached by the use of a feed-back amplifier.[2,3,4,5]

METHOD

The two voltages will be resolved into their symmetrical components in accordance with the methods developed by C. L. Fortescue.[6]

Although systems of polyphase vectors may be resolved into numerous equivalent systems,[7] the 2-phase system, a special case of 4-phase, may be and usually is resolved into two right-angled systems of opposite phase order.[8,9,10,11]

The main-winding voltage and the control-winding voltage, therefore, are resolved into two balanced 2-phase voltages of opposite phase sequence. The positive-sequence voltage produces positive-sequence current only and the negative-sequence voltage produces negative-sequence current only.[12,13] Total current and torque are found by the principle of superposition.[14,15]

For analytical purposes it is helpful to think of a polyphase induction motor operating on unbalanced voltages as equivalent to a system consisting of two identical motors mechanically coupled, one having impressed upon its windings the positive-sequence components of the unbalanced voltages and the other motor the negative-sequence components.[16,17]

This method of analysis has been tested in the laboratory and in practice and has been found to give good results when applied to standard polyphase induction motors under varying degrees of unbalance.[18,19,20] When applied to the servomotor with stationary "rotor" iron that is the drag cup motor, and the usual analytical assumptions[21] are met on the average, good agreement between experimental results and theory may be expected.

MATHEMATICAL DETAILS

Referring to Figure 1, which schematically represents the control motor in operation, the motor voltages V_M and V_C will be resolved into the two systems shown in Figure 2, as discussed previously. The voltage V_C must be expressed in terms of the drop through Z_C and the voltage E_C.

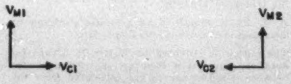

Figure 2. Symmetrical components of 2-phase voltages

From symmetrical component theory

$$V_M = V_{M1} + V_{M2} \tag{1}$$

$$V_C = V_{C1} + V_{C2} \tag{2}$$

From Figure 2

$$C_{C1} = -jV_{M1} \tag{3}$$

$$V_{C2} = jV_{M2} \tag{4}$$

Therefore

$$V_C = -jV_{M1} + jV_{M2} \tag{5}$$

$$jV_C = V_{M1} - V_{M2} \tag{6}$$

Adding equations 1 and 6

$$V_M + jV_C = 2V_{M1} \tag{7}$$

Likewise

$$V_M - jV_C = 2V_{M2} \tag{8}$$

From observation of Figure 1

$$V_C = E_C - I_C Z_C \tag{9}$$

It is assumed that

$$E_C = -jkV_M \tag{10}$$

where

$$k = \frac{|E_C|}{|V_M|} \tag{11}$$

and is regulated by the requirements of the control system.

Also from symmetrical component theory

$$I_C = I_{C1} + I_{C2} \tag{12}$$

$$I_{C1} = \frac{V_{C1}}{Z_1} = \frac{-jV_{M1}}{Z_1} \tag{13}$$

$$I_{C2} = \frac{V_{C2}}{Z_2} = \frac{jV_{M2}}{Z_2} \tag{14}$$

Where Z_1 and Z_2 are the impedances to positive- and negative-sequence currents in the motor respectively. Examples of the numerical calculation of these values from the induction motor equivalent circuit are in the literature.[10,18,19]

From equations 9, 10, 12, 13 and 14

$$V_C = -jkV_M - \left(-\frac{jV_{M1}}{Z_1} + \frac{jV_{M2}}{Z_2}\right)Z_C \tag{15}$$

From equations 7 and 15

$$2V_{M1} = V_M + j\left[-jkV_M + \left(\frac{jV_{M1}}{Z_1} - \frac{jV_{M2}}{Z_2}\right)Z_C\right] \tag{16}$$

and from equations 8 and 15

$$2V_{M2} = V_M - j\left[-jkV_M + \left(\frac{jV_{M1}}{Z_1} - \frac{jV_{M2}}{Z_2}\right)Z_C\right] \tag{17}$$

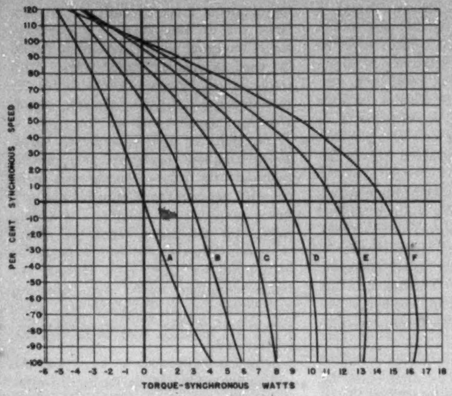

Figure 3. Per cent synchronous speed versus torque in synchronous watts for servomotor operating with $Z_c=0$

Curve "A" is for control voltage corresponding to $k=0$; "B", $k=0.2$; "C," $k=0.4$; "D," $k=0.6$; "E," $k=0.8$; "F," $k=1.0$

Equations 16 and 17 simplify as follows

$$V_{M1}=\frac{\frac{V_M}{2}\left[1+k+\frac{Z_C}{Z_1}\right]}{1+\frac{Z_C}{2Z_1}+\frac{Z_C}{2Z_2}} \tag{18}$$

$$V_{M2}=\frac{\frac{V_M}{2}\left[1-k+\frac{Z_C}{Z_1}\right]}{1+\frac{Z_C}{2Z_1}+\frac{Z_C}{2Z_2}} \tag{19}$$

These are the voltages applied to the two identical 2-phase motors fictitiously connected on the same shaft. The resultant torques can be calculated from the equivalent circuit noting that when the positive sequence motor is operating at a slip S_1, the negative sequence motor is operating at a slip $S_2=2-S_1$. Torque in synchronous watts is equal to the loss in the part of the equivalent circuit representing the rotor. Since the equivalent-circuit elements are considered constant, the torques on the two motors are proportional to the squares of their applied voltages. Negative-sequence torque subtracts from positive-sequence torque, because the negative-sequence voltage produces a magnetic field in the motor to which it is applied that is opposite in rotation to the shaft. Under these conditions the net torque is given by the following equation

$$T=T_{B1}\left(\frac{V_{M1}}{V_M}\right)^2-T_{B2}\left(\frac{V_{M2}}{V_M}\right)^2$$

synchronous watts (20)

Where T_{B1} is the torque produced by applying balanced 2-phase voltage of magnitude V_M to the motor windings at slip S_1 as read from a curve similar to curve "F" of Figure 3, and T_{B2} is taken from the same curve but at slip S_2. Examples of torque calculations are given in Appendix II.

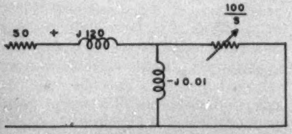

Figure 4. Servomotor equivalent circuit used in calculating performance curves

Balanced polyphase conditions

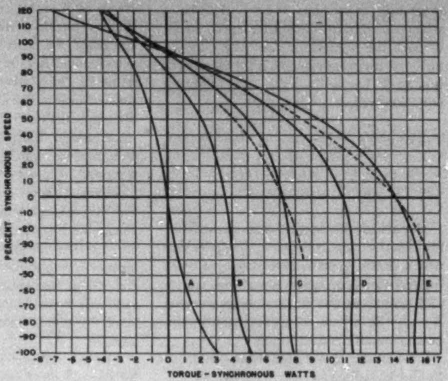

Figure 5. Per cent synchronous speed versus torque in synchronous watts for servomotor operating with $Z_c=200+j0$ ohms

Curve "A" is for control voltage corresponding to $k=0$; "B," $k=0.5$; "C," $k=1.0$; "D," $k=1.5$; "E," $k=2.0$

In the case where the control winding is supplied from a feed-back amplifier so that Z_C approaches zero, equations 18 and 19 are greatly simplified, for setting $Z_C=0$

$$V_{M1}=\frac{V_M}{2}(1+k) \tag{21}$$

and

$$V_{M2}=\frac{V_M}{2}(1-k) \tag{22}$$

For single-phase operation $Z_C=\infty$. The making of this substitution in both equations 18 and 19 results in the inde-

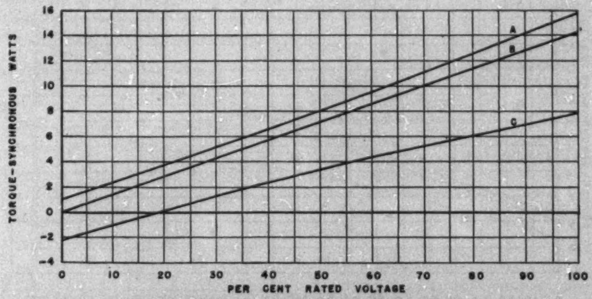

Figure 6. Torque in synchronous watts versus control-winding voltage expressed in per cent of rated voltage for servomotor operating with $Z_c=0$

Curve "A" is for 30 per cent synchronous speed in the reverse direction, or braking action; "B", zero speed; "C", 60 per cent synchronous speed in the normal direction terminate expression ∞/∞. However, when the derivative with respect to Z_C of both the numerator and the denominator of these expressions is taken according to l'Hospital's rule, the following equations result

$$V_{M1}=\frac{V_M Z_1}{Z_1+Z_2} \qquad (23)$$

$$V_{M2}=\frac{V_M Z_2}{Z_1+Z_2} \qquad (24)$$

Equations 18 and 19 are rather formidable for calculation. A simplification which holds approximately over a very limited range of speed about the standstill point can be made by considering $Z_1=Z_2=Z$, where Z is the motor impedance with blocked rotor.

On making this assumption equations 18 and 19 reduce to

$$V_{M1}=\frac{V_M}{2}\left[1+\frac{kZ}{Z_C+Z}\right] \qquad (25)$$

and

$$V_{M2}=\frac{V_M}{2}\left[1-\frac{kZ}{Z_C+Z}\right] \qquad (26)$$

Servomotor Performance—Application of Literal Analysis

STEADY-STATE PERFORMANCE

Control-Circuit Voltage Finite, but Different from Main-Winding Voltage. Figure 3 shows the speed-torque curves for control voltages corresponding to k values of 1.0, 0.8, 0.6, 0.4, 0.2 and 0 applied directly to the control winding of a motor having the equivalent circuit shown in Figure 4. This is the equivalent circuit of a control motor with stationary rotor iron as described previously. In separating the rotor and stator reactances, always a difficult problem with squirrel-cage rotors, the rotor reactance was considered to be zero inasmuch as it is relatively small because of the absence of conductors embedded in iron slots. Because of the large air gap, the exciting susceptance is so much larger than the conductance that this branch was considered purely inductive.

Figure 5 shows the speed-torque curves for the control winding voltage applied through a 200-ohm resistor, for k values of 2.0, 1.5, 1.0, 0.5 and 0. The curves are of steeper slope over the usual operating range near zero speed. The dash lines are obtained by use of the approximate equations 25 and 26 and are shown for comparison.

The calculations of torque are expedited by the use of the speed-torque curve for balanced operation, curve "F" of Figure 3. For any particular speed, the impedances Z_1 and Z_2 are calculated from the equivalent circuit Figure 4. These values are fed into equations 18 and 19, 23 and 24, or 25 and 26, whichever pair applies and the values of the positive- and negative-sequence voltages, V_{M1} and V_{M2}, are calculated.

Torque is then found by equation 20 and the speed-torque curve for balanced voltage.

When the control voltage is applied directly, the calculations are much simpler. The positive and negative components of voltage are given by equations 21 and 22. Torque is again found by equation 20. The speed-torque curve for balanced voltage on which the torques for the unbalanced conditions are based is calculated by the methods given in any standard text on a-c machinery or it may be obtained experimentally. However, since the exciting current is relatively large, the exact equivalent circuit should be used in making calculations. This curve is usually made available by the manufacturer of the control motor. However, usually only half the curve is given, that for positive-sequence speed. If the complete curve were given by the manufacturer from +100 per cent speed to −100 per cent speed, it would not take many minutes to calculate the data points for the whole family of curves shown in Figure 3. In fact, it would be economical of time even though the balanced-voltage curve were obtained experimentally to calculate the other curves rather than to obtain them experimentally.

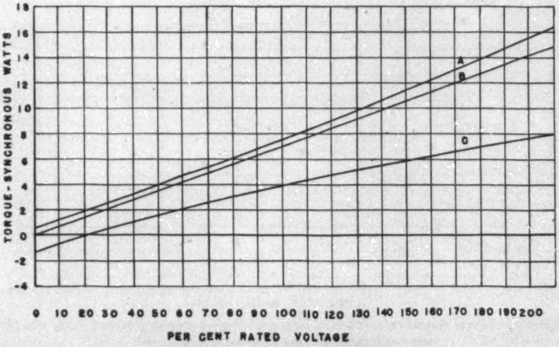

Figure 7. Torque versus control-winding voltage for servomotor operating with $Z_c=200+j0$ ohms, otherwise the same as Figure 6

It is not too serious to have only the positive-speed half of the balanced-torque curve given, as the remaining portion can be estimated with fair accuracy. Since V_2/V_M will be smaller than V_1/V_M for all cases except that of $V_C=0$, the effect of errors in the estimate will be reduced. At zero speed, of course, the calculation may be expected to be accurate, because this point is usually given on the torque curve for balanced voltage. This method has been used in the laboratory with good results.

Figures 6 and 7 show the validity of the assumption regarding linearity of torque with control voltage. The curves show that over a limited speed range this is nearly true. That it is exactly true at zero speed (assuming no variation in equivalent-circuit parameters with voltage) can be shown easily as follows

$$T=T_{B1}\left(\frac{V_{M1}}{V_M}\right)^2-T_{B2}\left(\frac{V_{M2}}{V_M}\right)^2 \qquad (20)$$

but at zero speed

$$T_{B1}=T_{B2}=T_B$$

therefore

$$T_0=\frac{T_B}{V_M^2}[V_{M1}^2-V_{M2}^2] \qquad (27)$$

Since
